Dr. Michael Shelby, Director  
Center for Evaluation of Risks to Human Reproduction  
National Institute of Environmental Health Sciences  
P.O. Box 12233, MD EC-32  
Research Triangle Park, NC 27709

Dear Dr. Shelby:

As a member of the Expert Panel for the CERHR-NTP Methanol Report, I wish to offer these comments on the final report dated April 2002. My commentary relates to both the content of the report and the process by which the report was prepared. In addition, my comments on the substantive aspects serve to highlight the main reasons for my formal dissent from Section 5 of the report. My intent is to offer constructive thoughts bearing not only on the Methanol Report itself but other reports that the CERHR may produce in the future.

One of my fundamental concerns about the Methanol Report pertains to risk communication. In Section 5.3, Overall Conclusions, the key message of the report is distilled to four bullet statements. These bullet statements may well be the only part of the report that many people will ever read. The statements indicate that, at blood methanol levels below 10 mg/L, the Panel had "minimal concern" about developmental toxicity in humans and "negligible concern" about male reproductive toxicity in humans. "Concern" (unmodified) is expressed about developmental toxicity if pregnant women are exposed specifically to "high levels" (undefined) of methanol. However, no expression of concern is registered regarding female reproductive toxicity, because of a lack of data. Most readers will interpret these conclusions as implying that essentially no concern is warranted regarding developmental or reproductive toxicity from methanol exposure in the general population. In my view, this is not the message the Methanol Report should convey. I say this for the following reasons.

First, the animal toxicity data on which the conclusions are based are, by the Panel's own characterization, "limited," "fragmented," "uneven," and, in some respects, "insufficient" (Methanol Report, p. 108). It is difficult to understand how one leaps from such limited data to confident assertions that essentially no concern is warranted about reproductive or developmental toxicity in humans from methanol exposure at other than "high levels." If the database were ample, robust, and consistent, then a conclusion of "no likely effect" might be warranted. That is not the case here. Instead of emphasizing the uncertainty of the available data, however, the Overall Conclusions offer assurances to the public and stakeholders, including those with a commercial interest in methanol fuels, that only "high" exposure levels, typically associated with accidental ingestion, pose a concern with respect to methanol toxicity hazards.
Second, the Overall Conclusions imply that methanol exposures are either "low-level" (blood methanol concentrations below 10 mg/L) or "high-level" (blood concentrations unspecified). This false dichotomy fails to recognize the likelihood of population exposures that are intermediate, that is, higher than "low" but less than the high levels associated elsewhere in the report with accidental exposures, especially ingestion. This intermediate exposure segment likely comprises individuals who use methanol in hobbies (e.g., model airplane fuels) or as a solvent (e.g., for cleaning purposes); also, increased usage of methanol fuels for motor vehicles could greatly expand the percentage of the population exposed to intermediate levels of methanol. Such exposures may be of particular concern with respect to reproductive and developmental effects because the critical period of exposure sufficient to induce adverse outcomes could be relatively brief.

The effect of the dichotomy between low and high exposures is to foster the misleading impression that one need not be concerned about exposure to methanol unless one makes the unfortunate mistake of ingesting the substance. As I understand the CERHR guidance to the Expert Panel on formulating conclusions, the lack of empirical data on intermediate population exposures means that considerations about this portion of the total population cannot be incorporated into the Overall Conclusions, because it would be "speculative." It seems terribly paradoxical that a reasonable inference about the distribution of population exposure levels cannot be entertained, whereas an inference of essentially no concern can be justified on the basis of limited and fragmented data.

A third but no less important point relates to susceptible populations. Again, the CERHR guidance requires "hard" information about the existence of such populations before they can be included in any expression of concern about the potential health hazards of methanol. Acknowledging elsewhere in the report that "subpopulations of undefined size may exist" but not including in the Overall Conclusions any reference to groups having diminished metabolic capacity to handle methanol (as is well established for ethanol) seems to be yet another case of a double standard for what constitutes sufficient evidence. In effect, in the face of scientific uncertainty the Methanol Report, reflecting CERHR guidance, places the burden of proof on those who would advocate some caution regarding the potential toxicity hazards of methanol rather than on those who, in this instance, have claimed that methanol poses essentially no concern.

Finally, it is difficult to reconcile the fourth bullet conclusion regarding the insufficiency of data on female reproductive effects of methanol with the omission of female reproductive function from the list of Critical Data Needs in Section 5.4. Readers might well interpret this incongruity as implying that the Panel did not judge potential effects of methanol on female reproductive function to be a matter of concern, regardless of whether data exist or not. Presumably, this is not the message that the CERHR or the National Toxicology Program intends to convey.
The net effect of the above omissions and constraints is an understated expression of concern about the potential health hazards of methanol. I believe it would have been possible to articulate a judgment on this matter that would have been more scientifically accurate and reflective of the collective views of the Panel, as well as being more consistent with the "Guidelines for CERHR Expert Panel Members." The CERHR Guidelines document (p. 14) states: "Although strict categories of potential risk are not prescribed for use by the panels, the narrative conclusions should qualify the likelihood of an adverse effect under specified exposure conditions using terms such as unlikely, likely, or highly likely." Consistent with this guidance, the Panel's conclusions could have been stated in a more scientifically credible manner by saying, for example, "The Panel concluded that methanol exposures resulting in low (<10 mg/L) blood methanol concentrations are unlikely to result in developmental toxicity in humans." Additional qualification regarding susceptible populations would be necessary, but the basic statement is descriptive and easily understood by the general public. It also better reflects the reality that expert panels deal with weights of evidence and imprecise probabilities, not discrete categories of concern, or the lack thereof. In any event, my point is that satisfactory alternatives to communicate the Panel's collective judgment could have been adopted.

Although my comments thus far have been framed in terms of risk communication, I trust that they are understood as having significant implications for the substance of the Methanol Report and are not viewed as just fine points of semantics or word-smithing. If the CERHR reports are to serve a useful public health function, I believe it is very important to avoid overstating judgments about either hazards or lack of hazards. To avoid such overstatements, uncertainty – whether it pertains to susceptible populations, exposures, or some other factor – needs to be appropriately reflected in the final judgments of the Panel. To put aside scientific uncertainty in formulating the Overall Conclusions does not serve the public well.

My other major area of comment relates to the process by which the Methanol Report was created. I perceived a tendency among the panelists, myself included, to focus on their respective assigned areas. This is not unexpected, but it made it difficult to "see the forest for the trees" and made the actual meeting of the Panel less productive than it could have been. More interaction among panelists prior to the meeting would have counteracted the tendency toward a narrow division of labor and would thereby have facilitated accomplishing the ultimately most important task of formulating the Overall Conclusions. Interaction could have been encouraged by an explicit request from CERHR to the Panel to use E-mail communications addressing all members rather than having individual members interact only with CERHR or its contractor. In addition, one or more conference telephone calls could have been scheduled at appropriate stages in developing the draft document. Such interactions would not only have served as a stimulus for each individual to keep up with his or her own assignment but would also have provided an opportunity to see how different areas of the document compared and related to each other. Except for the difficulty in scheduling a conference call, these steps are simple and cost virtually nothing.
In addition, the Panel Meeting itself should include adequate time for the members to interact. In my experience with World Health Organization workgroups for Environmental Health Criteria and Air Quality Guidelines, a full week is typically scheduled for these meetings. Although the nominal scope of coverage may be greater in the WHO documents, the critical endpoints and key studies usually are not substantially different in number and extent from the material covered in the case of the Methanol Panel Meeting. An additional day or at least a half day would have probably enabled the Panel to identify, discuss, and resolve issues that eventually surfaced after the meeting last October. Even with more interaction through Email and conference calls prior to convening the Panel, at least three full days should be allotted for these meetings, in my view.

If these measures had been in place, the Methanol Report could have been completed relatively easily and quickly, I believe. However, in the face of several questions not only about the expression of the Overall Conclusions but about factual errors and omissions in Section 5, I was concerned and remain concerned that the process of resolving issues subsequent to the Panel Meeting needs to involve, and be open to, the entire Panel. As just one example, the missing pages from the 1986 NEDO report, which I identified and provided to the CERHR contractor, were evidently never provided to members of the Panel. The pages in question included a table showing reductions in brain weight in a two-generation rat study that had been replicated in a special ancillary study. Although it may be debatable whether these missing pages would have warranted a change in the Overall Conclusions, I felt they were significant enough to merit reconsidering the characterization of the NEDO study by the Panel. If nothing else, omission of this information creates the impression that the Panel failed to consider all relevant information. Addressing this matter would not have been difficult, costly, or time-consuming. On the other hand, some of the factual errors I noted in the Report after the October Panel Meeting were readily corrected. It is not clear why some of my recommended corrections were accepted whereas others were not. If the entire Panel were involved in, or at least kept informed of, the resolution of such issues, it would help avoid the appearance of being arbitrary in accepting or rejecting the views or recommendations of individual Panel members.

As noted above, one of the flaws in the Methanol Report, in my view, is that the Critical Data Needs section does not identify female reproductive function as a specific data gap, despite the Overall Conclusion that data for this endpoint are insufficient. I believe this incongruity occurred primarily because of the limited time devoted to identifying and discussing critical data needs during the Panel Meeting. I doubt that the Panel as a whole intended to omit female reproductive function as a critical data need, and it would have been a relatively simple matter to have the Panel consider this matter by Email after the meeting. However, communications to the Panel seemed to focus more on closure on the Report than on making sure the document was as accurate and rigorous as it could be. It is understandable that procedural kinks need to be worked out as the CERHR matures. However, in my view, procedures and schedules should never become an end in themselves and should not be allowed to outweigh the more important considerations of quality, credibility, and protection of public health.
I hope that you will find my comments on the substance and process related to the Methanol Report to be helpful and constructive. These comments reflect my personal views and do not necessarily represent the position or policies of the U.S. Environmental Protection Agency.

Sincerely yours,

J. Michael Davis, Ph.D.
Senior Scientist

Dear Dr. Shelby,

I am glad to see this report has finally been released since it demonstrates a lot of work for all of the review panel. I do however, share many of the concerns that made me unable to sign the consensus statement of the final conclusions.

In brief my concerns relate to issues that originate in the review process and in the risk communication aspects of the final conclusions. I am still concerned that the process that led up to the final conclusions still misses the mark with respect to risk communication. I believe it is important to state clearly that the absence of data or uncertainties in the data do not signify a lack of risk as stated in the final conclusions of minimal and negligible risk.

The panel could not agree about the significance of the outcomes in the primate study of Burbacher et al., 1999 but the CERHR report's conclusions in essence sidestep this issue. I believe it is important to state when experts can not arrive at consensus about data that relates to risk communication. The panel agreed that the critical effects of methanol exposure were developmental effects and that the parent compound was the protoxicant. The panel also agreed that the metabolism of ethanol was sufficiently similar to ethanol. I continue to express concern that this similarity in metabolism, teratological outcomes in mice and the Burbacher study raises concern for more data on low dose exposure and effects on the developing nervous system at doses that do not produce overt teratology. I think more effort is needed in characterizing exposure and effects in potential susceptible populations. There is significant evidence that there are significant subpopulations that are at increased risk to ethanol's developmental toxicity due metabolic deficiencies that often arise from genetic polymorphisms that impair alcohol detoxification (e.g., alcohol dehydrogenase and specific P450 isoforms). This issue is mentioned in the CERHR report's conclusions but it is not explicitly noted as a critical data need for future risk assessment. The panel agreed the critical effects of methanol exposure were developmental effects in the fetus. It seems inconsistent that the fetus and child are the susceptible population which we are most concerned about but susceptible populations issues are not listed as a critical data for risk determination. This seems almost counter-intuitive, since we identified
the critical effect were adverse developmental outcomes. Who are the populations at risk should be an explicit part of the panel considerations.

Again, I reiterate that I do not think that the process that the panel went through for the evaluation of methanol adequately addressed susceptible populations concerns. I hope this issue will be discussed more extensively in future CERHR panel reports and will be included in the framework for all considerations of future chemical evaluations. What do we know was the featured question of the evaluation process with little or no emphasis on what we need to know about sensitive subpopulations in order to evaluate risk (e.g., pregnant women with genetic polymorphisms that limit detoxification capacity of methanol).

I believe the panel needs more than one meeting to address all these issues and the ground rules of the meeting need to be more explicitly stated and discussed prior to the consideration of the final face to face meeting. This process could be revised with a conference call that allows for discussion of the ground rules, the process, and the goals of the process followed by a one day face to face meeting to discuss the data summaries prior to the concluding meeting where the critical studies are discussed and the conclusions and consensus or lack of consensus statement are worked out for the final report.

I believe the final NTP report can address some of these concerns.

NTP-CERHR EXPERT PANEL REPORT
on REPRODUCTIVE and DEVELOPMENTAL
TOXICITY of METHANOL

JULY 2001  NTP-CENTER-XXXXX-00
also exposed 8 female *Macaca fascicularis* monkeys/group to 10, 100, or 1,000 ppm methanol vapors for 22 hours/day for up to or to 29 months and reported a non-dose- and time-related hyperplasia of “reactive astrocytes” in the nervous system. Methanol exposure had no effect on bodyweight or hematological or pathological parameters. Kavet and Nauss (2) noted that a critical review of the NEDO studies and results was not possible because the reports did not contain sufficient amounts of technical data and histopathological results.
PREFACE

The NTP-CERHR is headquartered at NIEHS, Research Triangle Park, NC and is staffed and administered by scientists and support personnel at NIEHS and at Sciences International, Inc, Alexandria, Virginia.

1.0 CHEMISTRY, USE, AND HUMAN EXPOSURE

The majority of information in this section was obtained from reviews. Because quality reviews have already been conducted, CERHR is basing the exposure evaluation on those review instead of starting de novo. There were some cases where the primary paper was reviewed, for example newer studies and key papers. The primary reviews utilized in this section were IPCS (1) and Kavet and Nauss (2). The Kavet and Nauss paper is the published version of an HEI (3) report. Because the Kavet and Nauss paper is more readily available to the public, it is being cited instead of the HEI report.

Some tables are presented to assist the reader in the interpretation of the data. Smaller tables are included in the text for the reader’s convenience and are designated as Table 1-1, 1-2, etc. Larger tables are included in Section 7 and are designated as Table 7.1-A, 7.1-B, etc.

1.1 Chemistry

1.1.1 Nomenclature
The CAS number for methanol is 67-56-1. Synonyms of methanol include: methyl alcohol, wood alcohol; Carbinol; Methylol; Wood; columbian spirits; colonial spirit; columbian spirit; methyl hydroxide; monohydroxymethane; pyroxylic spirit; wood naphtha; and wood spirit (4).

1.1.4 Technical Products and Impurities

According to IPCS (1), sales grade methanol in the U.S., must meet the following specifications:
There are no known trade names for methanol. Past or present manufacturers of methanol include Air Products and Chemicals, Ashland Oil, Inc, Atlantic Richfield Co, Borden Chemicals and Plastics Partnership, E I du Pont de Nemours and Company, Inc, Eastman Kodak Co, Georgia Gulf Corporation, Hq, Hoechst Celanese Corp, Hq, Quantum Chemical Corp, Hq, Tenneco Inc, Hq, and Texaco Inc, Hq (5).

1.2 Use and Human Exposure

1.2.1 Production

In the past, methanol was produced from the dry distillation of wood. Today methanol is primarily made from steam reformed natural gas and carbon dioxide (6). It can also be produced from biomas by the catalytic conversion of pressurized synthesis gas (hydrogen, carbon monoxide and carbon dioxide) in the presence of metallic heterogeneous catalysts (/).

Methanol is among the highest ranking production volume chemicals. In 1998, U.S. methanol production capacity totaled more than 2.2 billion gallons, which was approximately three-quarters of the U.S. demand (6). The remainder was imported, principally from Canada, for a total of approximately 3 billion gallons.

Table 1-2 lists production volumes for methanol in past years as reported by HSDB (5):

1.2.2 Use

About 70% of methanol manufactured worldwide is used as feedstock for the production of chemicals such as formaldehyde, methyl tertiary butyl ether (MTBE), acetic acid, methyl methacrylate, and dimethyl terephthalate (/). Methanol is widely used in a variety of consumer products, as described below. It is also used in the treatment of wastewater and sewage.
1.2.3 Occurrence

There is a high potential for release of methanol to the environment as a result of its large production volume, widespread use, and physicochemical properties (1). Methanol releases usually occur from usage of methanol-containing solvents and products, methanol production, end-product manufacturing, and storage and handling losses. Based on the 1992 Toxics Release Inventory (TRI), EPA estimated that methanol was the most released chemical to the environment through air, water, and land (1). The 1998 TRI Data Release for methanol presented a total on- and off-site annual release of close to 215 million pounds (7). Currently, methanol is one of the highest ranking chemicals in terms of environmental releases. According to the Toxics Release Inventory (8), methanol ranked second only to hydrogen chloride in both total air emissions and total on- and off-site releases in 1999. Because only certain types of facilities are required to report to the TRI, the data may not include all releases.

Persistence, bioconcentration, or bioaccumulation of methanol in the environment are not expected due to its low absorptive properties and rapid degradation. Methanol is readily degraded by photooxidation and the half-life for reaction with hydroxyl radicals is 7–18 days. Methanol is also biodegradable under aerobic and anaerobic conditions. About 70% of methanol in sewage systems is biodegraded by 5 days (1).

Humans are also exposed to methanol through natural sources. Methanol is a natural component of fruits, vegetables, and fermented spirits. Natural emission sources of methanol include volcanic gasses, vegetation, microbes, and insects. Methanol occurs naturally in humans and animals and can be found in blood, urine, saliva, expired air, and mother’s milk (1). Metabolism of the artificial sweetener, aspartame can also result in exposure to methanol (see Section 2.1.1.1).

1.2.4 Human Exposure

General Population Exposure

The general population can be exposed to methanol through environmental sources such as air and water, contact with methanol-containing products, and dietary sources such as fruits, fruit juices, aspartame, and alcoholic beverages.

Environmental exposures are outlined in Tables 7.1-A and 7.1-B. Most environmental exposures to methanol vapor are orders of magnitude below the occupational time-weighted average threshold limit value of 200 ppm (260 mg/m³) for an 8-hour day and 40-hour week (9). Typical rural exposures below 0.0008 ppm (0.001 mg/m³) and typical urban exposures approaching 0.03 ppm (0.04 mg/m³) have been reported (1). The American Forest & Paper Association (10) used data from the TRI database and local meteorological conditions in a screening model to estimate average 24 hour ambient methanol concentrations of 0.1-4.5 mg/m³ near 10 plants representing major methanol-emitting industries. According to the authors, the screening model used was conservative and likely to overestimate methanol concentrations. At the request of the EPA, “Tier 3” modeling for 12 of the largest-methanol emitting facilities was conducted and an upper limit of 2.5 mg/m³ ambient methanol concentration was estimated, thus demonstrating that the values first obtained with the screening model were overestimated. The EPA also requested that all sources emitting ≥500 tons methanol be identified; using the screening model it was estimated that the maximum predicted 24 hour concentration at or near the property line of these sites was 7.58 mg/m³. There is no known quantitative information about methanol concentrations in drinking water, but IPCS does report levels of methanol in wastewater samples (Table 7.1-B).
Consumer exposure to methanol can occur during use of methanol-containing products such as varnishes, shellacs, paints, windshield washer fluid, antifreeze, adhesives, deicers, and Sterno heaters. Methanol vapor may also be present in cigarette smoke at a level of 180 – g/cigarette (1). While much of the potential human exposure to methanol from the above uses is expected to be through inhalation, important exposure routes also include ingestion and dermal absorption. For oral ingestion, the consumption of adulterated alcoholic beverages or fermented spirits containing wood alcohol, as well as accidental or intentional consumption of pure methanol, are major sources of exposure. Dermal contact with methanol solutions can lead to rapid absorption, as discussed in Section 2.1.1.1.

A potential source of general population exposure to methanol is in motor vehicle fuels. Methanol is currently used as an alternative fuel to a limited extent, primarily in a mixture of 85% methanol and 15% gasoline known as M85. Because of a lack of infrastructure support for such fuels, M85 use is generally limited to fleet vehicles in certain areas. According to the Department of Energy (http://www.eia.doe.gov/cneaf/alternate/page/datatables/table1.html), approximately 18,000 vehicles capable of operating on M85 fuel were in use in 2000. These vehicles are typically equipped with “flexible fuel” engines that can run on mixtures ranging from 100% gasoline to 85% methanol:15% gasoline. It is therefore difficult to ascertain the actual frequency of usage of M85 in the population of flex-fuel vehicles. According to Department of Energy estimates (http://www.eia.doe.gov/cneaf/alternate/page/datatables/table10.html), approximately 1 million gallons of M85 was used in the United States in 2000 (compared to about 125 billion gallons of gasoline). Methanol is also receiving considerable attention as a potential fuel for fuel cells in motor vehicles. Fuel cell technology appears to be developing rapidly, but it remains to be seen whether methanol will become a major contender in the fuels market for this technology.

Given the limited and as yet unknown potential for future growth in the use of methanol fuels, population exposure to methanol in relation to mobile sources cannot be characterized at present. However, some estimates and limited measurements of methanol air concentrations associated with methanol fuel provide a perspective on potential individual exposures to methanol vapors. Early estimates of ‘worst case’ exposure levels for methanol vapor concentrations in residential garages spanned a broad range of values, up to 200 ppm and possibly higher (2). These estimates varied greatly for different scenarios, e.g., whether the engine met emission standards or was malfunctioning, or whether the engine was idling or in a ‘hot soak’ condition (evaporation from a hot engine after it had been turned off). Additional estimates have assumed a vehicle under “hot soak” conditions with a malfunctioning emission control device. More recently, actual empirical measurements of evaporative emissions from such a vehicle were made by Tsai and Weisel (17). The authors measured methanol and other VOCs in a garage and attached home as a function of several variables. A vehicle was operated on M85 until fully warmed up and then parked in an attached garage with the garage door closed, the door between the garage and the adjacent room in the house closed, and the door between the adjacent room and the remainder of the house closed. Among the variables manipulated was the emissions control device on the vehicle, namely the charcoal canister hose connection, which was left either connected or disconnected to simulate a malfunctioning device. The highest methanol levels were measured in the garage when the canister hose had been disconnected. Under those conditions, the average (mean) concentration was 0.99 ppm, and the maximum measured concentration was 1.3 ppm. With the hose in place, the mean concentration was 0.50 ppm and the maximum was 0.75 ppm. With the hose disconnected, levels in the adjacent room were 0.12 ppm (mean) and 0.23 ppm (maximum), and somewhat lower in the remainder of the home (mean: 0.056 ppm; maximum: 0.11 ppm).
Streicher (12) measured methanol vapor concentrations from the fuel system of a vehicle with a malfunctioning emission control device (methanol-saturated canister). In this study M100 fuel was used and the measurements were made in a sealed chamber approximately 2/3 the volume of a one-car garage. After 6 hours (the maximum interval of the study) the methanol vapor concentration was about 270 ppm at 94 degrees F and about 97 ppm at 75 degrees F. Using a model based on these and other data, Streicher (12) estimated that a methanol concentration of approximately 230 ppm could occur in a well-sealed one-car garage, given “cold-soak” conditions for 6 hours at 100 degrees F ambient temperature.

The above estimates and measurements cannot be considered representative of potential population exposure levels that would occur under a much wider range of conditions. Also, a more complete exposure assessment would take into consideration the potential for inhalation of vapors during refueling. Other, less common scenarios that are part of general population exposures include the use of such fuels as solvents (e.g., by do-it-yourself mechanics) and accidental spillage. Each of the latter scenarios could involve dermal as well as inhalation routes of exposure. No estimate of potential integrated exposure exists at present for these situations that are presumably at the high end of a distribution of population exposure levels.

One type of potential accidental exposure to methanol warrants special note. Each year several thousand cases of accidental ingestion of gasoline are reported to U.S. poison control centers. Litovitz (13) analyzed 1987 data from U.S. poison control centers and found that 39% of accidental ingestions involved teenage and young adult males (15-29 years old), almost all of which occurred during the course of siphoning to transfer fuel from one container to another. Nearly as many cases (36%) involved children under six years of age. Most of the latter cases occurred when the children found a used beverage container in which gasoline was stored. With gasoline, the primary toxicity hazard lies in the possibility of regurgitating the fuel and aspirating the vomitus, which can induce chemical pneumonitis. However, if M85 were substituted for gasoline in these situations, methanol would considerably increase the potential for serious morbidity or mortality. Litovitz (13) noted that ingestion of as little as 5 ml (about a teaspoonful) of M85 fuel by a 10 kg one-year-old child could require invasive treatment (hemodialysis) and as little as 12 ml (less than a tablespoonful) could result in death. Allowing for unreported cases and extrapolating from 1987 U.S. poison control centers data, Litovitz estimated an annual incidence of 35,000 accidental ingestions of gasoline in the United States and 52,000 cases of gasoline poisonings by any route.

The general public is also exposed to methanol through diet (Table 7.1-C). Methanol occurs naturally in fresh fruits and vegetables as either free alcohol, methyl esters of fatty acids, or methoxyl groups on polysaccharides. Lindinger et al. (14) noted an increase in breath methanol levels in 4 males who ate 1 kg apples and drank 75 g of 40%/60% ethanol/water. Fruit juices contain methanol or methanol precursors and a range of 12-640 mg methanol/L in juice with a mean of 140 mg/L has been widely quoted (1, 2, 15).

Alcoholic beverages contain methanol at concentrations ranging from 6–27 mg/L in beer, 96–329 mg/L in wine (16 IPCS, 1997 #140), and up to 1,500 mg/L in some neutral spirits (1)). Taucher et al. (17) demonstrated an increase in the breath methanol levels of subjects consuming 100 mL brandy; however the Panel noted that the study does not provide useful information since breath methanol levels were not correlated with blood levels.

Another source of methanol exposure is the ingestion of the artificial sweetener aspartame, which releases methanol when it is metabolized. Typically, 10% by weight of ingested aspartame is
hydrolyzed to free methanol, which is then available for absorption (1). Table 1-3 lists some products that can contain aspartame and the amount of aspartame used in the product (18).

The FDA estimated aspartame exposures by 3 methods (18). The first estimate used the Bureau of Foods method of assuming that aspartame is used to replace all sucrose in the diet for a 60 kg man and a value of 8.3 mg/kg bw/day was obtained. The second estimate used dietary survey information from the Market Research Corporation of America (MRCA) that includes dietary information collected from 12,000 individuals over a two week period. Estimates conducted according to the MRCA method are particularly relevant to a CERHR review because food intake levels were included for various age groups including children. The estimates included intake of aspartame through carbonated beverages and other potential uses during that time period. With this method, the 99th percentile was estimated to be 34 mg/kg bw/day for all age groups including children. Table 1-4 lists mean and 90th percentile values for adults and children in the highest exposure groups.

*Methanol exposures would be 10% of the values reported in the table.

The third method for estimating aspartame intake was by assuming substitution of all carbohydrate requirements including sucrose with aspartame (18). Using this method, a maximum usage of 23-25 mg/kg bw/day was calculated for a 70 kg adult and a value of 19 mg/kg bw/day was calculated for a 10 kg infant.

Stegink (15) reported that aspartame-sweetened beverages have about 555 mg aspartame/L (56 mg/L methanol) at a typical soft drink sweetness level (10% sucrose w/v; aspartame sweetness about 180 times that of sucrose). IPCS estimated that consuming a 354 mL carbonated beverage sweetened with aspartame is equivalent to ingesting 20 mg methanol (1).

Occupational Exposure

Occupational exposure to methanol may occur during its production or result from its presence in refrigeration systems, as an inhibitor of hydrate formation at natural gas pipeline pumping stations, and as a component in the production of formaldehyde, MTBE, acetic acid, and other industrial chemicals (1). Methanol’s proposed use as a substitute for petroleum fuels may result in greater environmental releases to the air through vehicle emissions and at fueling stations. One
report indicated that concentrations measured during refueling of methanol-powered transit buses were “generally less than 10 ppm” in the breathing zone of the workers (19). Air concentrations for mechanics who were changing fuel filters for these buses averaged around 50 ppm during the 2-minute procedure, during which levels reached as high as 2200 ppm.

From the 1950s to the 1980s, teacher aids and clerical workers were exposed to methanol concentrations ranging from 362–3,052 ppm (475–4,000 mg/m$^3$) during the operation of “spirit” duplicator machines (1). Those workers experienced symptoms of methanol intoxication as described in Section 2.2.1

Currently the OSHA permissible exposure limit (PEL) and ACGIH threshold limit value (TLV) are set at 200 ppm (260 mg/m$^3$) (5, 9). The ACGIH short term exposure level for methanol is 250 ppm (9). Assuming worker exposure levels within the TLV and PEL, an 8-hour work day, an inhalation rate of 20 m$^3$/day (20), and a 70 kg body weight, CERHR estimated worker exposures to methanol to be below 25 mg/kg bw/day:

\[
<260 \text{ mg/m}^3 \times 20 \text{ m}^3/\text{day} \times 8 \text{ hour/24 hours} \times 1/70 \text{ kg} = <25 \text{ mg/kg bw/day}
\]

The biological exposure index (BEI) for urinary methanol at the end of an 8 hour shift is 15 mg/L (9).

1.3 Utility of Data

1.4 Summary of Human Exposure

Methanol is produced naturally in the human body and is found in expired air and body fluids. Significant additional methanol exposure to humans occurs through contact with natural and anthropogenic sources. Methanol is used in the manufacture of other chemicals and in consumer products such as varnishes, paints, windshield washer fluid, antifreeze, adhesives, deicers, and Sterno heaters. Methanol is also used in the artificial sweetener, aspartame, which releases 10% by weight methanol when metabolized. There currently is limited use of methanol in gasoline, but developments in fuel cell technology could result in much greater use of methanol in the future. Natural sources of methanol include fruits and vegetables, fermented spirits, volcanic gasses, vegetation, microbes, and insects.

Humans can be exposed to methanol by inhalation, dermal contact, or oral intake; however most exposures are not well characterized. General population exposure through ambient air is expected to be low since a limited number of measurements in U.S. air demonstrated levels below 0.05 ppm (1). Time weighted inhalation exposures in occupational settings are expected to be below the ACGIH TLV of 200 ppm. Dietary exposures to methanol are not well characterized with the exception of methanol exposure through the intake of aspartame. Based on FDA (18) estimates of aspartame intake for all ages, the mean and 99th percentile values for methanol ingestion are ≤1.1 and 3.4 mg/kg bw/day, respectively. Methanol intake through natural dietary sources such as fruits and vegetables is thought to be equivalent or greater to that of aspartame. Exposure to methanol through dermal contact has not been characterized. Although methanol may be used as an alternative or supplement to gasoline, and could be used in the future in fuel cells, estimates of inhalation exposure to methanol vapor in relation to fuel usage have thus far been highly variable and uncertain, with 'worst case' levels ranging into the hundreds of ppm's (2).
The current prevalence of accidental ingestions and dermal contacts involving gasoline in storage containers, especially among young children, raises concerns about the potential for similar exposures to methanol if the latter were to become more widely used as a fuel. The relatively greater acute toxicity of methanol compared to gasoline warrants attention to such potential exposure conditions.
2.0 GENERAL TOXICOLOGY AND BIOLOGICAL EFFECTS

2.1 Toxicokinetics and Metabolism

The majority of information in this section was obtained from reviews. Because quality reviews have already been conducted, CERHR is basing the toxicokinetics evaluation on those reviews instead of starting de novo. There were some cases where the primary paper was reviewed, for example newer studies and key papers. The primary reviews utilized in this section were IPCS (1) and Kavet and Nauss (2). The Kavet and Nauss paper is, in the main, the published version of an HEI (3) report. Because the Kavet and Nauss paper is more readily available to the public, it is being cited instead of the HEI report.

Some tables are presented to assist the reader in the interpretation of the data. Smaller tables are included in the text for the reader’s convenience and are designated as Table 2-1, 2-2, etc. Larger tables are included in Section 7 and are designated as Table 7.2-A, 7.2-B, etc.

2.1.1 Absorption

2.1.1.1 Humans

Methanol is rapidly absorbed following inhalation, ingestion, and dermal contact, and the absorption capabilities do not appear to differ substantially across mammalian species (1). Several recent studies have measured background blood methanol levels in humans and those values are summarized in Table 7.2-A. A mean pre-exposure blood methanol level of 0.6 mg/L was observed in a study of 12 healthy males after 12 hours on a restricted diet (no alcohol, diet foods and drinks, fruit and fruit juices, and coffee) (21); Chuvers et al. (22) reported background serum methanol levels in 26 volunteers after 24 hours on a restricted diet (no coffee, vegetables, fruit, alcohol, or aspartame) to be 1.8 ± 2.6 mg/L (mean ± standard deviation). Lee et al. (23) reported a mean endogenous blood methanol level of 1.82 mg/L in 5 subjects who were allowed to eat a breakfast consisting of non-aspartame containing cereal and no fruit juices. In studies where alcohol intake was restricted in subjects for 24 hours, Batterman et al. (24) and Batterman and Franzblau (25) reported mean background methanol blood levels of 1.7–1.9 mg/L. The Panel notes that widely cited studies by Stegink et al. (15, 26) used an analytical method for methanol in blood with a limit of detection of 4.0 and 3.5 mg/L, respectively. This value is approximately ten-fold greater than methods used in studies over the last 15 years.

Oral Exposure

A study monitored the blood disposition of methanol in fasted human adults given 34, 100, 150, or 200 mg/kg aspartame in 300 ml orange juice (15). There was no mention of dietary restrictions for subjects. The size of the lowest dose group was 6 males and 6 females, while that of each of the other groups was 3 males and 3 females. In the 34 mg/kg group, the blood methanol concentrations were below the detection limit (4.0 mg/L) in all subjects. At doses of 100 mg/kg aspartame and higher, dose-related increases in blood methanol and urinary formate were observed. No significant increases in levels of blood formate were seen at any dose. Mean peak blood methanol concentrations (± standard error) were 12.7 ± 4.8, 21.4 ± 3.5, and 25.8 ± 7.8 mg/L at 100, 150, and 200 mg/kg aspartame, respectively, and were achieved at 1 to 2 hours post-exposure. The area under the blood methanol concentration-time curve (indicative of
cumulative methanol exposure) increased proportionally to aspartame dose (4.19 ± 1.12, 8.71 ± 1.41, and 9.51 ± 1.69 units, respectively). Eight hours after dosing, blood methanol levels returned to pre-exposure levels in the 100 mg/kg group. Twenty-four hours after dosing, levels returned to pre-exposure levels in all groups. In the 200 mg/kg group, urinary formate excretion was significantly increased up to 8 hours post-exposure (34 ± 22, 101 ± 30, 81 ± 22, and 38 ± 12 µg/mg creatinine in pre-exposure, 0-4 hour, 4-8 hour, and 8-24 hour post-exposure samples, respectively). No significant effects on blood chemistry parameters were observed.

**Strengths/Weaknesses:** This is a carefully conducted study with proper controls, adequate number of subjects (n=30), and attention paid to dietary factors. The limit of detection for blood methanol was ten-fold greater than for methods used in more recent studies. As a result the time course of blood serum values at the lowest dose tested (an aspartame dose equivalent to 3.4 mg/kg methanol) is limited.

**Utility (adequacy) for CERHR evaluation process:** This aspartame study demonstrates that (1) blood methanol concentrations increased in a dose-related manner, and (2) there was no increase in blood formate, even at the highest challenge dose that is equivalent to a methanol exposure of 20 mg/kg. This study will be useful in the evaluation of methanol.

A study in twenty-four 1-year-old infants (26) measured blood methanol concentrations after oral exposure to aspartame. In a series of studies, 10 infants were exposed to 34 mg/kg aspartame (the 99th percentile of adult daily ingestion), 6 infants were exposed to 50 mg/kg (termed a very high dose), and 8 infants received 100 mg/kg (described as an “abusive” dose). Methanol is a hydrolytic metabolite of aspartame accounting for 10% of aspartame consumed. Thus, these authors estimated the aspartame doses studied to be equivalent to ingestion of 3.4, 5 and 10 mg/kg bw methanol. Aspartame was administered via a cherry-flavored beverage. There was no mention of dietary restrictions for subjects. A fasting blood sample and three subsequent samples were obtained from each subject. The authors observed a positive correlation between aspartame dose and blood methanol level in the infants which was similar to that observed in a previous study of similar design and dose in adults (15). Mean blood methanol levels were at the limit of detection (3.5 mg/L) in infants administered 34 mg/kg aspartame. Infants administered aspartame at 50 mg/kg had peak blood methanol values of 3.0 ± 1.0 mg/L thirty to ninety minutes after aspartame dosing. These values were essentially the same values as those seen in adults, 3.4 ± 1.2 mg/L, receiving an equivalent dose. The eight infants administered the 100 mg/kg aspartame dose had a peak mean blood methanol value of 10.2 ± 2.8 mg/L ninety minutes after dosing. In comparison, the mean blood methanol concentrations in six adults administered an equivalent dose of aspartame was 12.7 ± 2.0 mg/L sixty minutes after dosing. While the responses in infants and adults at this dose were similar, the serum levels peaked earlier in adults and appeared to persist longer when one compared the area-under-the-curve throughout a 2.5-hour sampling period.

**Strengths/Weaknesses:** A strength is the total number of subjects tested (24) and an ability to compare these results with adult values that used similar dosing and experimental methods. A weakness is the lack of raw data; one has to obtain blood methanol levels from the figures. Further, the analytical detection limit in this study is ten-fold less sensitive than methods used by many other authors which prevents critical comparison of response of infant and adult at the lowest doses tested.

**Utility (adequacy) for CERHR evaluation process:** This reference provides a useful comparison of blood methanol levels in one-year-old infants and adults. Blood levels seen
following high doses were not significantly different from those seen in adults receiving similar
doses indicating that aspartame is metabolized to methanol in a similar manner.

Table 7.2-B includes blood levels of methanol and formate that were measured by Stegink et al.
(15, 26).

Davoli et al. (27) also administered aspartame to humans and measured methanol levels in blood
with a method that results in lower detection limits. Four healthy adult males fasted for 8 hours,
drank no alcoholic beverages for 24 hours, and consumed no fruit juices or fruits or vegetables
for 18 hours prior to the study. Blood methanol levels were measured by gas chromatography
prior to exposure and at 0, 30, 45, 60, 90, 120, and 180 minutes following ingestion of 500 mg
aspartame in 100 ml tap water. According to the authors, that dose of aspartame is equivalent to
6-8.7 mg/kg bw for a 58-80 kg person and is within the range of average daily intake for
aspartame if it replaced all sucrose in the diet. Blood methanol in the subjects prior to exposure
was 1.4-2.6 mg/L. Following aspartame administration, blood methanol levels were significantly
increased at 30, 45, and 90 minutes. The peak exposure occurred at 45 minutes post-exposure,
with a mean incremental increase of just below 1.0 mg/L. Methanol levels dropped at 1 hour,
rose at 90 minutes, and then consistently declined through the remainder of the experiment. The
authors noted that the incremental increase of methanol was within the same order of magnitude
for variations in endogenous methanol levels. They also stated that when aspartame is divided
into a number of small doses, the incremental increase in methanol levels would not be detectable
or significant.

**Strengths/Weakness:** To be evaluated.

**Utility (adequacy for CERHR Evaluation Process):** To be evaluated.

**Inhalation Exposure**

Experiments in which human volunteers were exposed to moderate levels of methanol vapor have
occasionally demonstrated increases in blood and urine methanol concentration. However, as is
seen with oral exposure to methanol, levels of plasma formate are not increased following
inhalation exposure to about 200 ppm methanol. Methanol blood levels obtained during various
exposure scenarios are outlined in Table 7.2-B.

In a pilot study designed with an objective to assess neurobehavioral effects, twelve male
volunteers were exposed in a chamber to 250 mg/m³ (191 ppm) methanol for 75 minutes (21). A
more complete summary of the study is found in Section 2.2.1. Following methanol exposure,
subjects exhibited no change in plasma formate concentration, which remained at a mean of
0.08 mmol/L. These same subjects exhibited increases in mean plasma and urine methanol
concentrations of about 3.3- and 2.5-fold, respectively.

**Strengths/Weaknesses:** This study was a rigorously controlled (double blind) study that used
dietary controls, up-to-date, carefully validated methods for measuring blood methanol and
formate levels, and appropriate QA/QC and statistical procedures. The exposure dose is most
relevant to occupational exposure as the dose studied was the current threshold limit value (TLV).
The report is well documented. The number of subjects is adequate to note statistically
significant differences if they exist. One can have a great deal of confidence in the quality and
accuracy of the data.
This was a pilot study whose primary objective was to explore possible neurobehavioral effects. It utilized a single exposure dose of methanol and a single exposure period, which was relatively short (75 minutes). Therefore, it was not possible to construct dose-response information. In addition kinetic studies were not done.

**Utility (adequacy) for CERHR evaluation process:** This study provides very useful information on blood and urinary levels of methanol and formate in human subjects before and after a 75-minute exposure to either 250 mg/m$^3$ of methanol vapors or filtered air. Given the limited information that is available on human exposures to methanol and the quality of this study, the blood methanol and formate data are useful to the CERHR Panel. Pre-exposure levels of methanol in blood are given as approximately 0.6 mg/L. This work demonstrates that when humans are exposed to TLV levels of methanol, formate does not accumulate above background levels in blood.

Osterloh et al. (28) and Chuwers et al. (22) reported the methanol concentrations in a randomized double-blinded study of the potential neurobehavioral effects of methanol on a group of 26 volunteers (15 male, 11 female) exposed to 200 ppm (262 mg/m$^3$) methanol for 4 hours in an exposure chamber. This study is described in Section 2.2.1 under Chuwers et al. Each subject was exposed twice: once to methanol and once to water vapor. In each instance, blood samples were collected before exposure, every 15 minutes for the first hour, every 30 minutes for the next 3 hours, and every hour for 4 hours post-exposure. Urine samples were collected before exposure (hour 0), at the end of exposure (hour 4), and 4 hours after the end of exposure (hour 8). Outlier analysis resulted in the removal of 4 subjects from the final results, due to the removal of four or more data time points; thus, the results were presented for 22 subjects.

Pre-exposure serum values for the water vapor (control) and methanol phases of the study were 1.0 ± 0.6 and 1.8 ± 2.6 mg/L, respectively. Peak methanol concentration in blood serum (6.5 ± 2.7 mg/L) occurred at the end of the 4-hour exposure, then declined during the 4-hour post-exposure period, although not to pre-exposure levels. All levels measured at various exposure and post-exposure times were significantly increased (by at least 4 times at the peak levels) compared to controls. Serum and urine formate levels were not significantly increased at any point during exposure or post-exposure (pre-exposure serum formate values for control and methanol phases of the study were 10.3 ± 5.5 and 11.2 ± 9.1 mg/L, respectively). Serum methanol concentrations from hour 0 to 8 were adequately described by either a biphasic linear or logarithmic function. No covariance of methanol concentrations with age, sex, weight or folate level was seen.

**Strengths/Weaknesses:** This is a well designed and reported study that had the appropriate controls. Strengths of the study include: appropriate dietary restriction; large number of subjects (22/26); up-to-date procedures for measuring methanol and formate; multiple sampling times.

Only one dose of methanol was used, therefore no dose-response can be calculated. However, the authors did report some kinetic data. Under these exposure conditions, 200 ppm for 4 hours, serum and urinary formate levels did not increase.

**Utility (adequacy) for CERHR evaluation process:** This study is highly useful because it provides reliable information on serum and urinary methanol and formate levels following a well-controlled exposure to 200 ppm methanol vapors for 4 hours.
In an experiment by Lee et al. (23), 6 male volunteers (29–55-years old) were exposed to 200 ppm (262 mg/m$^3$) methanol vapor in a chamber for 6 hours. During this period, subjects were either at rest or under physical exercise (6 alternating 20-minute periods on a stationary cycle followed by a 20-minute period of rest). This exercise was calculated to increase respiratory rate such that methanol inhalation was increased 1.8 times. Blood was collected at pre-exposure and post-exposure, and methanol levels were measured using an analytical method with a detection limit of 0.4 mg/L. On each day of the experiment, subjects could eat cereal with no aspartame, but could not drink fruit juice. Five pre-exposure blood methanol concentrations were given for three subjects. The mean and SD were 1.82 ± 1.21 mg/L; the range was 0.57 to 3.57 mg/L. After a 6-hour exposure at rest, blood methanol levels had increased from a mean of 1.82 to 6.97 mg/L; after a 6-hour exposure with exercise, blood methanol levels had increased from a mean of 1.9 to 8.1 mg/L. When mean blood methanol concentration of the exercise group was compared with that of the at-rest group, no statistically significant difference was seen, even though pulmonary ventilation had increased 1.8 times (10.5 to 18.6 L/min). While blood methanol levels had increased, no statistically significant differences in pre- or post-exposure blood formate concentrations were seen in volunteers exposed to methanol vapor under either a resting or exercise regimen. Pre-exposure mean blood formate levels were 9.08 ± 1.26 μg/mL and the post-exposure mean level was 8.70 μg/mL in the group at rest; with exercise, the mean blood formate level was 8.78 μg/mL pre- vs. 9.52 μg/mL post-exposure.

**Strengths/Weaknesses:** The strengths and weaknesses of this study are similar to those cited above for Cook et al. (21). There were fewer subjects in this study (n=6), but the exposure period was longer (6 hours). The study did indicate that six-hour exposure to 200 ppm methanol did elevate blood methanol levels ~3 to 4-fold without any accompanying increase in blood formate.

**Utility (adequacy) for CERHR evaluation process:** The study is a useful source of data on background blood methanol and formate levels and also provides data on blood and formate levels after exposures relevant to the workplace, i.e., six-hour exposure at 200 ppm, the current TLV.

Batterman et al. (24) conducted studies to determine the relationship between methanol concentrations in blood, urine and breath in volunteers exposed to methanol vapors. There were two groups studied. The core group consisted of four female volunteers (ages 41–60 years) exposed to 800 ppm (1,048 mg/m$^3$) methanol for 30, 60, and 120 minutes (2 replicates for each, plus a third replicate for 120 minutes) in an exposure chamber. Total number of exposure sessions were 25 (4 subjects x 3 durations x 2 replicates + 1 with a third exposure). The second group consisted of three additional females and 12 males who were exposed to 800 ppm methanol during 8-hour sessions and 12 control sessions. Periodic breath, blood, and urine samples were collected. No volunteers had occupational or avocational exposure to methanol. Baseline or endogenous concentrations of methanol in blood averaged 1.8 ± 0.7 mg/L. The half-life of methanol in blood was determined from the 30- and 120-minute exposures to be 1.44 ± 0.33 hours. Breath and urine data were also used to estimate half-life, compensating for mucous membrane desorption and voiding time. Results were similar to blood but more variable results were obtained. Data adequately fit a first-order model, with the exception of post-exposure times of 0, 15, and 30 minutes. The first-order model and the estimated half-life suggested that methanol concentrations in blood do not increase linearly with exposure duration, but asymptotically approach steady-state level. Breath data were fit better with a 3-compartment (fast and slow desorption from mucous membranes and end-expired or alveolar air) than a 2-compartment model.
**Strengths/Weaknesses:** The strengths of this study are the well-controlled exposures and sampling procedures. The use of multiple exposure times and the comparative information on blood, urine, and breath methanol are also positive features. There are some weaknesses in the study design. It appears that different subjects were used for the first set of exposures (0 to 120 minutes) and the second set (8 hours). Alcoholic beverages were restricted 24 hours prior to testing but there were no other dietary restrictions. The inhalation exposure dose (800 ppm) was much higher than the U.S. TLV and is unlikely to be encountered.

**Utility (adequacy) for CERHR evaluation process:** Despite the limitations cited above, the study provides useful information on blood, breath and urine methanol levels under very high exposure conditions. Useful kinetic data – again under these exposure conditions - were also provided.

A study by Heinrich and Angerer (29) examined blood and urinary levels of methanol in workers of a pesticide manufacturing plant, but was not included in this document due to errors in the reporting of concentration units.

Inhalation studies with humans have shown a net absorption of methanol of 60 to 85% (1). In a group of 22 volunteers exposed to 200 ppm (262 mg/m³) methanol for 4 hours, the mean apparent absorption half-life was 0.80 ± 0.55 hours (28). Lung retention of inhaled methanol does not vary significantly with exposure concentration or ventilation rate. Five healthy men, exposed for 8 hours to methanol concentrations of 103 to 284 mg/m³, had mean ventilation rates of 9.7 to 11.2 L/min; lung retention, as determined from methanol concentration in inspired and expired air, ranged from 53.4 to 61.3% (Table 2-1) (30). During exercise, the ventilation rate of the subjects increased by 2.5-fold, but the lung retention of methanol did not change significantly.

**Table 2-1. Mean Percent Lung Retention Of Inspired Methanol In Human Subjects, Sedivec et al. (30).**

**DermaL Exposure**

Methanol is readily absorbed through the skin. Upon direct skin contact with pure methanol, absorption is rapid, and cases of methanol poisoning in children exposed dermally have been reported (31, 32).

Dutkiewicz et al. (33) compared the amount of unchanged methanol that was excreted after administration of identical doses through skin or by mouth. Six human volunteers were exposed dermally to methanol by attaching a flat glass applicator containing methanol onto a 11.2 cm²
surface area of the forearm. Absorption periods of 15 to 60 minutes were used. The absorbed dose was calculated from the amount applied to the skin and the amount of methanol recovered from the skin after the exposure period. Methanol levels in urine (every hour for 8 hours) and exhaled air (every half-hour to hour 2.5, then at hours 4 and 5) were also measured after a 20-minute immersion of the hand (435–445 cm² surface area) in methanol. Three subjects were also given oral doses of methanol (1.67 g), and urine and exhaled air samples were then taken. The authors estimated that immersion of one hand in liquid methanol for 2 minutes would result in a body burden of up to 170 mg, which is similar to that resulting from inhaling approximately 40 ppm methanol for 8 hours. The mean calculated absorption rate of methanol through human skin resulting from 22 experiments in 6 subjects was 0.192 mg/cm²/min. Absorption rate peaked at 30 minutes post-exposure. Excretion also peaked at 30 minutes post-exposure in the oral and hand immersion experiments.

Strengths/Weaknesses: This is an older (1980) study and the analytical methodology procedures are only briefly described. There was no direct measure of methanol absorbed, i.e., concentration in blood.

Utility (adequacy) for CERHR evaluation process: This study demonstrates the importance of the dermal route of exposure. There is limited confidence in the absolute values presented.

Batterman and Franzblau (25) reported on a study of dermal exposure to neat methanol in human volunteers. Seven men (ages 22–54) and five women (ages 41–63) were the study subjects for a total of 65 sessions and had no occupational or avocational exposure to methanol, formic acid or formaldehyde. All refrained from alcohol consumption during the 24-hour period prior to a session. Two males were smokers. Methanol exposure occurred by immersing one hand for 0 to 16 minutes in a vessel that contained neat methanol. Exposure sessions for each volunteer were spaced at least a week apart. Blood samples were taken 15 and 10 minutes prior to exposure and at 0, 15, 30, and 45 minutes, 1, 1.5, 3, 3, 4, 5, 6, and 7 hours following the exposure. A two-compartment model was used to derive absorption rates and delivery kinetics. The mean background concentration of methanol in blood for all subjects was 1.7 ± 0.9 mg/L. The authors noted that average baseline values among the 12 subjects differed significantly and means ranged from 0.9 to 2.9 mg/L. The average baseline for females (2.4 ± 0.8 mg/L) was significantly higher than that for males (1.3 ± 0.8 mg/L). Methanol delivery into the blood began during or immediately after exposure and reached a maximum rate 0.5 hour after the exposure. The area-under-the-curve (AUC) was highly correlated with duration of exposure and blood concentration maximums. The average derived dermal absorption rate was 8.1 ± 3.7 mg/cm²/hour. The authors noted that their absorption rates (from hands) were similar to those reported by Dutkiewicz et al. (1980) for forearms. They further noted that these in vivo derived data were at least 6 times greater than those derived from in vitro results.

According to Batterman and Franzblau (25), EPA’s 1992 guidance on dermal exposure assessment recommends using a methanol absorption rate of 1.27 mg/cm²/hr. However, this rate was 6 times less than that derived in vivo in the current study (8.1 mg/cm²/hr), and almost 10 times less than that measured in vivo by Dutkiewicz et al. (33) (11.7 mg/cm²/hr).

Strengths/Weaknesses: This is a well conducted study that used good methodology, data was thoroughly presented, and appropriate statistical analysis performed. The study did not control for dietary sources of methanol exposure. They did, however, subtract individual background levels from data obtained.
Utility (adequacy) for CERHR evaluation process: These data provide a reliable estimate of dermal exposure. The similarity of results with the Dutkiewitz et al. study provides a basis for greater confidence in the absorption estimate from that older study. The data also reveal the variability of background methanol blood values across time with individuals and between individuals. These values are also greater than those given as the endogenous or background levels for the general population.

2.1.1.2 Animals

Methanol blood levels have been measured under various exposure scenarios in monkeys, mice, and rats and are summarized in Tables 7.2-C, 7.2-D, and 7.2-E, respectively.

Inhalation Exposure

The major objective of the multi-experiment study by Pollack and Brouwer (34) was to determine the distribution of methanol in female Sprague-Dawley rats (Hilltop Laboratories) and Crl:CD-1 mice [ages not specified] at different stages of gestation. Baseline studies were performed on non-pregnant animals after exposure by the intravenous or oral routes (dose range 100 to 2,500 mg/kg). The disposition of methanol was studied in pregnant rats on gestation days 7, 14 and 20 and in pregnant CD-1 mice on gestation days 9 and 18. Pesticide-grade methanol was used, which is 99.8% pure according to Tedia (35). In these studies, exposure was by the oral, intravenous, and inhalation routes (1,000 to 20,000 ppm for 8 hours). Saline was the vehicle for oral and intravenous exposure. Three to five animals were examined per dose and exposure condition. Methanol concentrations were measured in blood, urine, and amniotic fluid by gas chromatography (GC). Dose-dependent differences in kinetic parameters and influences of gestational stage were analyzed by analysis of variance (ANOVA). Differences in venous and arterial blood methanol concentrations were analyzed by paired Student’s t test. The authors developed major conclusions from their studies that are presented below:

- Methanol absorption is rapid and essentially complete following oral exposure.
- Over the methanol inhalation concentrations used in the study, decreasing absorption was seen in rats and mice. This is attributed to a decreased rate of breathing and a parallel lowering of absorption efficiency from the upper respiratory tract.
- Under the high exposure conditions used in the rodent studies, disposition is nonlinear in female rats and mice for all three routes of exposure. There are linear and nonlinear pathways for elimination of methanol; the relevant contribution of each pathway is concentration-dependant. The saturable nonlinear pathway seen at the 100 and 500 mg/kg doses, involves metabolism of methanol to formaldehyde and then to formic acid. A parallel linear route for elimination of methanol was observed that accounted for an increasingly significant fraction of total elimination as systemic concentration. This pathway is characteristic of passive-diffusion and, at the highest dose (2,500 mg/kg), accounted for nearly 90% of methanol elimination, with pulmonary and urinary clearance occurring in equal amounts.
- The rate of methanol accumulation in the mouse was two- to three-fold greater that that in the rat. This difference persisted notwithstanding the two-fold higher rate of elimination seen in the mouse. Plausible explanations put forth by the authors were the more rapid rate of respiration and more complete absorption in the nasal cavity in the mouse. They believe this may account for the greater sensitivity in this species to the teratogenic effects observed by others.
• Examining the bioavailability data as a whole, the authors concluded that systemic availability of orally administered methanol was similar in pregnant and non-pregnant animals. Minor changes in volume of distribution were noted, possibly related to re-compartmentalization of total body water as gestation progressed.

• Penetration of methanol from maternal blood to the fetal compartment appeared to be inversely proportional to maternal blood methanol concentration. The authors believe this is consistent with a possible decrease in blood flow to the fetal compartment.

Strengths/Weaknesses: This is a well conducted study. Appropriate procedures were used to generate methanol, measure respiratory parameters, and analyze blood methanol concentrations. The QA/QC procedures were excellent. The grade of methanol used was reported and chamber concentrations were monitored. The investigators chose inhalation exposure levels to approximate those of previous animal studies in which teratogenic effects of methanol had been demonstrated; however, these levels are orders of magnitude higher than those experienced in occupational or ambient settings. This is the major weakness of the study.

The authors do not comment on the fact that increased absorption observed in the mouse may have been due to the fact that, in addition to respiration rates, the mucus membranes in the nasal area are significantly thinner than in rats. This fact is critical to any extrapolation of these data to humans. Decreased absorption with increasing respiration rates and thickness of the nasal mucosa is consistent with the observation of Sedivec et al. (30), who reported the retention of inhaled methanol in humans to be 58%. Lastly, it was not reported if assignment to groups was random.

Utility (adequacy) for CERHR evaluation process: The results are very useful for comparing the two rodent species but only for the high-level exposure conditions that were used. The results have not been validated for ambient exposure situations. The interpretation of this study should include this limitation.

2.1.2 Distribution
Methanol distributes rapidly and uniformly to all organs and tissues in direct relation to their water content, with an overall volume of distribution of about 0.6 L/kg (1, 3).

2.1.3 Metabolism
An understanding of the metabolism of methanol is important since the toxic properties of methanol are associated with intermediate metabolites rather than the alcohol per se. There is an extensive data base on the metabolism of methanol with good reviews provided by IPCS (1), Kavet and Nauss (2), and Liesivuori and Savolainen (36). The narrative in this document is drawn from these reviews. However, Panel members did review the primary sources cited in these reviews to assure themselves that key statements are consistent with the primary literature.

In mammals, methanol is metabolized in a series of oxidation steps to sequentially form formaldehyde, formate and carbon dioxide. A schematic illustration of the overall metabolism of methanol in primates and rodents is represented in Figure 2-1.
Methanol can be oxidized to formaldehyde through three different pathways within the liver, although two are of primary importance. In primates, alcohol dehydrogenase catalyzes the metabolism of methanol to formaldehyde, whereas in rodents, the catalase pathway performs this function. Despite this difference, this first metabolic step proceeds at similar rates in non-human primates and rats. Formaldehyde is rapidly oxidized (half-life ~ 1 minute) to formic acid (formate + H⁺) and does not accumulate in animals or humans exposed to methanol. Formaldehyde dehydrogenase is found in liver, brain and erythrocytes and catalyzes a reaction of formaldehyde with reduced glutathione to form S-formyl glutathione, which subsequently hydrolyzes in the presence of glutathione thiolase to formic acid and reduced glutathione. Formate is primarily oxidized to carbon dioxide and water in mammals through a tetrahydrofolate-dependent pathway that is presented in Figure 2-2.

Figure 2-1. Metabolic Pathways And Primary Catalysts For Methanol Oxidation In Primates And Rodents.
Figure 2-2. Metabolism of formate through the folate pathway.

Formate combines with tetrahydofolate enzymatically to form 10-formyl tetrahydrofolate. Through another enzyme reaction, 10-formyl tetrahydrofolate is oxidized to carbon dioxide and tetrahydrofolate. The availability of tetrahydrofolate, derived from folic acid in the diet, is the major determinant of the rate of formate metabolism. In primates, the folate mediated oxidation of formate proceeds at one-half the rate observed in rats. There is substantial evidence that formic acid is the metabolite responsible for the visual and metabolic poisoning seen in primate species. In studies where severely toxic or lethal doses were administered the development of acidosis coincided with the accumulation of formic acid in blood with a parallel decrease of bicarbonate in plasma. In monkeys, it has been demonstrated that inhibition of tetrahydrofolate generation specifically affects formate oxidation but not methanol disappearance. Decrease in the folate metabolic pool prolongs blood levels by decreasing the rate at which formate combines with tetrahydrofolate. Tables 2-2 and 2-3 compare levels and activities of folate and folate enzymes in various species.

Data are from Johlin et al. (37) except those values designated by *, which are from Black et al. (38).

IPCS (1) stated that endogenous formate is generally present in human blood at levels of 0.07 to 0.4 mM. This level does not appear to be affected by methanol exposures within the range of those expected to be experienced by the general population (see Section 1). The background blood formate values from several recent studies are presented in Table 7.2-A. Values from selected exposures are included in Table 7.2-B.

In a study of 12 men exposed in a chamber to 250 mg/m³ (191 ppm) methanol for 75 minutes, no increase in mean plasma formate concentration was observed (0.08 mM before and immediately after exposure), indicating that elimination pathways were not saturated (21). In support of this hypothesis, mean urinary methanol concentration increased from 0.9 mg/L pre-exposure to 2.2 mg/L immediately post-exposure, and remained at that level when measured one hour later. Osterloh et al. (28) and Chuvers et al. (22) observed no significant increase in blood formate levels following inhalation exposure of 26 volunteers to 200 ppm methanol for 4 hours (11.2 mg/L pre-exposure and 14.3 mg/L post-exposure). Urine formate levels were only slightly higher at 0–4 hours post exposure compared to unexposed controls (2.2 mg/4 hour versus 1.7 mg/4 hours, respectively). Lee et al. (23) observed no significant increase in blood formate levels.
following inhalation exposure of 5 subjects to 200 ppm methanol for 6 hours; mean formate levels ranged from 8.7–9.52 mg/L both prior to and following exposure. In the inhalation studies, volunteers were subjected to various levels of dietary restriction that are discussed in Section 2.1.1.1. In an oral exposure study, Stegink et al. (15) noted that blood formate levels did not increase significantly in 6 adults administered 200 mg/kg bw aspartame (equivalent to 20 mg/kg methanol); mean blood formate levels were 19.1 mg/L prior to exposure and ranged from 11.2–22.8 mg/L during the 24-hour period after exposure. However, urinary levels of formate were significantly increased from background levels (34 μg/mg creatinine) at 0–4 hours (101 μg/mg creatinine) and 4–8 hours (81 μg/mg creatinine) after exposure, thus demonstrating metabolism of methanol to formate without saturation of metabolic capacity.

Studies in monkeys, mice, and rats have measured blood formate levels following various exposure scenarios and these values are listed in Tables 7.2-C, 7.2-D, and 7.2-E, respectively.

A study by Lee et al (39) illustrates the effects of folate deprivation on methanol disposition and toxicity in rats. Lee et al (39) reported that controlled dietary folate permitted the development of a rodent model whose toxicological response to methanol mimicked that seen in primates. Groups of five 4-week-old male Crl:Long Evans rats were fed one of three diets for at least 18 weeks that the authors designated as folate-sufficient, folate-pared, or folate-reduced (a folate-pared diet with 1% succinylsulfathiazole added to inhibit endogenous production of formate by gut flora). Body weights were measured weekly and liver samples were periodically taken for folate analysis. The authors stated that the rate of body weight gain was similar across all three groups. No differences in body weight changes were seen. Liver folate levels increased with time in the folate-sufficient group, but decreased in the folate-pared group to a steady-state level, and declined to an even lower steady-state level in the folate-reduced group to 10–30% control level. After a single gavage dose of 3,500 mg/kg methanol in water [purity not specified], blood methanol and formate levels were measured by GC in five rats/group. It appears that the dose was selected based on doses in monkey studies by McMartin et al. (40). Statistical significance between experimental groups was evaluated by the Dunnet’s t-test. A peak blood level of about 150 mmol/L methanol was seen in all groups, followed by a similar pattern of decline over 48 hours. Blood formate profiles differed significantly, however, with no accumulation in the folate-sufficient group, accumulation in the folate pared (8.3 mmol/L after 48 hours), and even greater accumulation in the folate-reduced group (18.7 mmol/L after 48 hours). Following a gavage dose of either 3,000 or 2,000 mg/kg methanol, a dose-related increase in blood formate was seen in folate-reduced (but not in folate-sufficient rats) to 9.2 mmol/L at 24 hours, and 15.6 mmol/L at 48 hours. The authors compared their results with published results in monkeys, in which oral exposure to 3,000 mg/kg produced a peak blood formate concentration of 7.4 mmol/L after 12 hours (40). Oral exposure to 2,000 mg/kg methanol produced a peak blood formate level at 24 hours post-exposure of 6.5 mmol/L and 8.1 mmol/L in the monkey and folate reduced rats, respectively. Formate level returned to normal by 48 hours post-exposure in the monkey whereas the level in folate-reduced rats was 11.7 mmol/L at 48 hours, and at normal level at 72 hours. Folate reduction increased sensitivity to methanol as noted by death in 8/11 folate-reduced rats after 4 days of exposure to 3,000 ppm for 20 hours/day; there were no deaths in folate-sufficient rats after 14 days of exposure. The study authors concluded that rats on their folate-reduced diet regimen were more sensitive than monkeys to methanol poisoning because they accumulated more formate than did monkeys at an equivalent level of exposure.

**Strengths/Weaknesses:** The strength of this study is the development of a rodent model that would be useful for studying methanol toxicity and the fact that a variety of inhalation and oral
exposure scenarios were used. Another strength of this study was that chamber concentrations of methanol were monitored. A weakness of this study is that the purity of methanol was not reported. (It was not stated if animals were randomly assigned to exposure groups). Comparisons between vitamin-deficient and normal animals usually include pair-fed controls that were not part of this study. However, Lee et al. did state that body weight gain was generally similar across all groups. The study does indirectly support the belief that the tetrahydrofolate pathway is critical to the disposition of formate.

Utility (adequacy) for CERHR evaluation process: This study provides information about a rodent animal model for folate deficiency that has not been physiologically characterized.

Several studies are presented below that provide insight into the metabolism and excretion of methanol in the non-human primate. The study by Burbacher et al. was published subsequent to the reviews from which this summary was developed.

An extensive methanol study was conducted in the non-human primate Macaca fascicularis (41). Toxicokinetic objectives were to assess whether repeated exposure to methanol changes methanol disposition kinetics, whether repeat exposure results in accumulation of blood formate, and whether methanol metabolism and disposition changes during pregnancy. In addition, the study assessed whether chronic methanol exposure at levels of 200–1,800 ppm was associated with overt adult toxicity, female reproductive toxicity or both, and whether in utero exposure to methanol affects offspring development. The reproductive and developmental portions of the study are found in Section 3.2.2 of this report.

A two-cohort study design utilized 48 adult females. See section 3.2.2 for details about animal ages and sources. For each cohort, 24 females were randomly assigned to one of four exposure groups and, after a baseline period of approximately 4 months, were exposed to 0, 200, 600 or 1,800 ppm methanol vapors (99.9% purity) for 2.5 hours per day, seven days per week. Doses were selected to produce blood methanol concentrations from just above background to just below levels resulting in non-linear clearance kinetics. Controls were exposed to air only in chambers. Methanol exposure occurred daily through an initial 4-month methanol exposure period, breeding, and pregnancy. Six-hour methanol clearance studies were performed after the initial exposure to methanol and after approximately 3 months of exposure; two additional clearance studies were performed during pregnancy. Blood methanol, formate, and folate concentrations were measured in 11–12 monkeys/group by GC, a colorimetric enzymatic assay, and radioimmunoassay, respectively. Statistical significance was evaluated using standard and repeated measures ANOVA models. Results (means ± SE in mg/L) of the biweekly monitoring of blood methanol concentrations are presented below.

The authors reported that endogenous blood methanol levels in female cynomolgus monkeys ranged from 2.2 to 2.4 mg/L (Table 2-4). As can be seen, there were no material differences in blood methanol values as a result of pregnancy. Values were ~2.4 (control), 5.0 (200 ppm group), 11.0 (600 ppm group) and 35 mg/L (1,800 group). Burbacher et al. noted a disproportionate blood concentration-to-exposure-level dose relationship when they compared mean, dose-normalized, and net blood methanol concentration-time profiles for the 600 and 1,800 ppm groups. This finding suggests saturation of the metabolism dependent (hepatic alcohol dehydrogenase) process that has also been reported by others.

Results (means ± SE in mM) of the biweekly monitoring of plasma formate concentrations are presented below in Table 2-5.

There were no differences in formate concentrations among the groups during the baseline period. There were significant differences (ANOVA; *p* = 0.005) between baseline and pre-breeding and from pre-breeding to pregnancy (ANOVA; *p* = 0.0001). These changes were not dependent upon dose. Serum folate levels were reported to be within the normal range of values for macaques; values during the baseline and pre-breeding phase were ~12–15 µg/L (Table 2-6). There were slight but significant changes in folate levels when the baseline and pre-breeding periods were compared as well as when pregnancy values were compared to those obtained prior to pregnancy. These differences were not dose-dependent.

Net blood methanol concentration-time data for the 600 and 1,800 ppm groups were fitted to a linear one-compartment first-order model or a saturable one-compartment Michaelis-Menten model. In these models, allometrically estimated ventilation rates, assumed ventilation rate, and fractional absorption were constant across exposure concentrations, and methanol uptake in the lung was constant throughout the exposure period. The data from the 600 ppm group adequately fit the linear model, while the majority of the data sets from the 1,800 ppm groups better fit the Michaelis-Menten model. These findings suggest saturation of methanol metabolism at high doses and are consistent with the findings of others who studied non-human primates (42). The half-life for blood methanol estimated from the linear model for the 600 ppm groups ranged from 55.4 to 90.7 minutes in the four exposure scenarios, while the half-life for the 1,800 ppm groups from the Michaelis-Menten fit ranged from 56.6 to 77.6 minutes.

**Strengths/Weaknesses:** Burbacher et al. is one of the best studies of methanol disposition in non-human primates available. The strengths of the study are:

- It was conducted in Macaque monkeys – a species that is similar to humans in its sensitivity to methanol. The animals were first separated into groups based on age, size, and parity, then randomly assigned to exposure groups.

- All procedures were carefully controlled and validated. Methanol concentrations in chambers were monitored and reported. Therefore, one can have a high degree of confidence in the absolute values reported in this study.

- Inhalation exposure was to environmentally relevant doses of methanol vapors as well as one dose that approached toxic levels. The methanol purity was reported.

- The study provides information on blood methanol and plasma formate levels following acute and chronic exposures.

- Blood values were determined in the same monkeys prior to and during pregnancy.

A possible weakness was the authors’ presumption that formate alone is the only toxic metabolite. In addition, there is a presumption that maternal blood methanol and formate levels are reliable predictors of what the fetus experiences; there are no empirical data from this study on placental or fetal tissue levels of methanol or formate.

**Utility for the CERHR Process:** The biochemical data in this study are highly relevant for the CERHR process because of the high quality of the study, the relevance of the animal model, the use of environmentally relevant doses of methanol and routes of exposure, and the availability of dose-response and kinetic information.

Dorman et al. (43) examined the pharmacokinetics of $[^{14}C]$methanol and $[^{14}C]$formate in normal and folate-deficient cynomolgus monkeys, *Macaca fascicularis*, following inhalation of environmentally relevant concentrations of $[^{14}C]$methanol. Four normal female 12-year-old
Cynomolgus monkeys were initially exposed for two hours to each of four different concentrations of \([^{14}C]\)methanol vapors (>98% purity): 10, 45, 200, and 900 ppm [13, 60, 260 and 1,200 mg/m\(^3\)] with each exposure separated by at least 2 months. The doses were based on likely exposure scenarios resulting from use of methanol as an automotive fuel and one higher dose. After this series of experiments, monkeys were fed a folate-deficient diet supplemented with 1% succinylsulphathiazole for 6–8 weeks to reduce serum folate concentration to <3 ng/mL serum and <120 ng/mL erythrocytes. The monkeys were then exposed to 900 ppm \([^{14}C]\)methanol for 2 hours. Folate deficiency did not affect hematocrit, RBC count, mean corpuscular volume, or mean corpuscular hemoglobin concentration. In each experiment, methanol was administered via an endotracheal tube while the animals were under general anesthesia. Blood samples were collected at time 0, 0.25, 0.5, 1, 1.5, and 2 hours into the exposure period, and at 3, 4.5, 6, and 7.5 hours post-exposure. Urine was collected during exposure and until 48 hours post-exposure. Methanol and formate levels in blood and urine were measured by high pressure liquid chromatography (HPLC). The Student’s t-test was used to determine statistical significance between results obtained under folate-sufficient and deficient conditions.

Blood methanol level peaked at the end of each 2-hour exposure and then declined to undetectable levels at 8–10.5 hours post-exposure. End-of-exposure methanol concentration, methanol AUC, and total amounts of \([^{14}C]\)methanol and \([^{14}C]\)carbon dioxide exhaled were linearly and significantly related to inhaled methanol concentration. The elimination half-life of methanol (<1 hour) was not significantly affected by inhaled methanol concentration. Urinary excretion of methanol was <0.01% absorbed dose at all doses, and no significant difference was seen in methanol urinary excretion or exhalation between folate-deficient and folate-sufficient monkeys exposed to 900 ppm methanol. The linear relation between inhaled methanol dose and blood methanol concentration AUC indicate that dose-dependent methanol metabolism and pharmacokinetics did not occur. Dorman et al. found no significant formate accumulation at any dose in folate-sufficient animals. The concentration in blood of \([^{14}C]\) methanol-derived formate from all exposures were 10 to 1,000-fold lower than endogenous blood formate concentrations of 0.1 to 0.2 mmol/L. This suggests that exposure to methanol vapor at low yet environmentally relevant doses does not result in elevation of formate levels. However, peak methanol formate level was significantly higher in folate-deficient animals compared to folate-sufficient animals exposed to the 900 ppm dose.

**Strengths/Weaknesses:** Strengths of the study are that it used a primate model, had an excellent exposure system, measured respiratory parameters, reported methanol purity, measured and reported methanol concentrations in test atmosphere, and used state-of-the-art procedures for measuring methanol metabolites and quantifying exhaled and excreted radiolabeled methanol.

Limitations in extrapolation noted by an HEI Review Committee (44) included: exposure was via an endotracheal tube, thus bypassing the nose; exposures were conducted under general anesthesia thus, the delivered doses of methanol are probably not comparable to those in animals breathing normally; and there was substantial variation among monkeys, and the statistical analysis may not have been optimal to account for this variation.

It should be noted that although \([^{14}C]\)-formate concentrations increased in the blood of folate-deficient monkeys exposed to 900 ppm methanol vapors, this represents only a small fraction of the total blood formate (estimated to be about 1%).

**Utility (adequacy) for CERHR evaluation process:** The Dorman et al. (43) study is highly relevant to the consideration of toxicokinetics, pharmacokinetic models, and mechanisms.
However, because the exposure conditions are not the same as those experienced by people, the absolute blood methanol and formate levels should not be directly extrapolated to humans.

The pharmacokinetics of methanol and formate were characterized in male F-344 rats (CDF(F-344)/CrIBR) and adult rhesus monkeys (Macaca mulatta, from Hazleton Laboratories) [age not specified for either species] (42). Based on data collected over 6 hour periods where intravenous and inhalation exposure occurred, the authors developed a physiologically-based pharmacokinetic model. Young adult Crl:CDF male rats and three young adult male Macaca mulatta primates were used in these studies. Two groups of four rats were given 100 mg/kg [14C]-methanol (>98% purity) in saline intravenously. One group was used to determine blood concentration-time course and cumulative urinary excretion of [14C]-methanol and 14C-formate. The second group was used to determine cumulative exhalation time courses of 14C-methanol and 14CO2. Four rats per concentration were exposed to methanol vapor (>99.9% purity) concentrations of 0, 200, 1,200 or 2,000 ppm [0, 260, 1,560 or 2,600 mg/m3] for 6 hours in a head-only chamber. Monkeys were individually exposed to atmospheres of 0, 50, 200, 1,200 and 2,000 ppm with 2-week recovery periods between exposures. [Rational for dose doses selected was not discussed]. In the inhalation experiment, blood methanol and formate levels were measured by GC. For the intravenous experiment, blood and urine 14C-methanol and [14C]-formate were measured by HPLC.

The intravenous studies indicated that 96.6% of methanol clearance was via metabolism with pulmonary and renal clearance accounting for 2.6 and 0.8%, respectively. A total of 1.7% of the dose was eliminated as 14C-formate in the urine. Blood methanol in rats reached a plateau after 1 hour of inhalation of 200 ppm methanol but continued to rise in the 1,200 and 2,000 ppm groups. Blood methanol levels after 6 hour exposure were 3.1 ± 0.4, 26.6 ± 2.0, and 79.7 ± 6.1 mg/L in the 200, 1,200 and 2,000 ppm groups, respectively. These end-of-exposure blood concentrations (and AUCs) were not proportional to exposure level, with the non-linearity most pronounced between the 1,200 and 2,000 ppm dose. Blood methanol concentrations in monkeys at the end of exposure were 3.9 ± 1.0, 37.6 ± 8.5, and 64.4 ± 10.7 mg/L at the 200, 1,200 and 2,000 ppm doses, respectively. No significant increase over background was observed at the 50 ppm dose. There was proportionality between exposure dose and blood concentration and AUC between 1,200 and 2,000 ppm. The peak blood formate concentrations in rats and monkeys ranged from 5.4 to 13.2 ug/ml; there were no statistically significant differences between the control and methanol treated groups.

Horton et al. stated that the lack of a discernable increase in blood formate in monkeys was not surprising and was consistent with estimates (3) of dose required to saturate folate-dependent metabolism of formate, i.e., 250 mg/kg. In modeling their monkey data, they noted that after inhalation of low concentrations of methanol the initial step of metabolism was compatible with rodent catalase. They further noted observations by others that high methanol concentrations were necessary to show that methanol was a substrate for rhesus monkey alcohol dehydrogenase. The authors stated that, while dose-dependent pharmacokinetics occurred in monkeys, blood methanol levels decreased in a mono-exponential manner, suggesting that repeated 6-hour exposures should not result in an accumulation of methanol in blood. They reported that this hypothesis was corroborated by exposing monkeys to 2,000 ppm 6 hours/day, 5 days/week for 2 weeks. Blood samples after the end of 1 or 2 weeks exposure showed that neither methanol nor formate had accumulated in the blood.

**Strengths/Weaknesses:**
The strengths of this study include:
• Primate model
• Rigorous monitoring and control of exposures, sampling procedures, and analyses
• Range of inhaled methanol doses (50 to 2,000 ppm) that included environmentally relevant doses. Purity of methanol was reported.
• Use of two species and comparison to human data (not cited in the above paragraph).
• Ability to compare kinetics following intravenous and inhalation routes of exposure.

The major weakness is the small number of animals (4 rats and 3 monkeys).

Utility (adequacy) for CERHR evaluation process: Very useful for the CERHR process.

2.1.4 Elimination

Information about methanol elimination was obtained from reviews by IPCS (1), Kavet and Nauss (2), and Liesivuori and Savolainen (36). After methanol is distributed in the body it is either directly excreted in urine and exhaled breath or metabolized in the liver. Clearance from circulation in humans following low-level exposures follows first-order kinetics with a half-time of ~2.5 to 3 hours. At higher doses the elimination becomes saturated. The kidney appears to exert no active control over urinary methanol concentration. Exhalation levels are proportional to methanol concentration in blood. While excretion by kidney and lung are linear (first-order kinetics), metabolic conversion is not a linear function of concentration. Biotransformation by sequential oxidation in the liver accounts for 96.9% of the elimination, while urinary excretion and exhalation account for the remainder. The presence of ethanol can slow the clearance of methanol from blood through metabolic pathways, a fact that is used in the treatment of methanol poisoning. Formaldehyde, which is formed as the first oxidation step in the metabolism of methanol, is metabolized to formate very rapidly with half-life of ~ one minute. The rate of formate elimination, the oxidation product of formaldehyde, is dose dependent as, discussed in Section 2.1.3.

A population of 84 non-occupationally exposed subjects (31 males, 53 females) in Sao Paulo, Brazil were assessed for urinary methanol in order to establish reference values for occupational biomonitoring (45). The cohort consisted of non-smokers or smokers of less than 10 cigarettes per day, non-frequent alcohol consumers, and non-users of aspartame. No significant differences in urine methanol levels were seen between males and females. Clinical signs (hemogram, glycosis, urea, creatinine, gamma-glutamyltransferase, alanine aminotransferase, aspartate aminotransferase, total cholesterol, triglycerides and urine type I) were within the normal range. The mean urinary methanol level was 2.26 ± 1.26 mg/L (standard deviation). The range of values was 0.50 to 4.78 mg/L.

Strengths/Weaknesses: This is an observational survey that provides some baseline information on urinary methanol levels in the general population. The subjects reportedly did not consume aspartame. Diet was not restricted with the exception of the exclusion of alcoholic beverages 24 hours preceding the urine sampling. Therefore, some subjects may have been exposed to methanol through the consumption of fruits and vegetables. It would have been useful to have some information on ambient methanol levels in the region.

Utility (adequacy) for CERHR evaluation process: For the reasons cited in the section above, this study is of limited utility to the Panel.
2.1.5 Pregnancy
A study in humans demonstrated that breakdown and excretion of folic acid is accelerated during the second and third trimesters of pregnancy (46). Additional details of the study are included in Section 3.1.

Pikkarainen and Raiha (47) measured in vitro alcohol dehydrogenase (ADH) activity in the livers of human fetuses, children, and adults (n=1-3/age group) using ethanol as a substrate. The ADH activity in 2-month-old fetal livers was about 3-4% that of adults. In 4-5 month old fetuses, ADH activity was roughly 10% that of adults, and in infancy activity was about 20% that of adults. ADH activity increased in children with age and at 5 years of age reached a level that was within the ranges noted for adults. Great variation was noted in adult ADH activity. The observations of ADH activity in fetal livers are qualitatively consistent with those observed in rats and mice by Ward and Pollack (48) and discussed under Section 3.2.3.

Available data in primates indicate little or no differences in methanol pharmacokinetics as a function of pregnancy (41). In rodents, methanol uptake and elimination was virtually unaffected by pregnancy (34). Pollack and Brouwer did report a statistically significant decrease in Vmax for formaldehyde formation in rat and mouse liver homogenate, a finding they described as relatively minor. Additional details for the Burbacher et al. (41) and Pollack and Brouwer (34) studies are in Sections 2.1.3 and 2.2.1.2, respectively.

2.1.6 Physiologically-Based Pharmacokinetic Models
A number of models have been developed specifically for methanol. Physiologically-based pharmacokinetic (PBPK) models incorporate species-specific parameters such as blood flow rates, tissue volumes and relative levels of blood perfusion, and known metabolic mechanisms. Once developed, PBPK models can then be validated using available data on the disposition of the chemical of interest in various species. Based on the validity of the model, a decision can then be made on its use for predicting human risk from chemical exposure. These models are briefly described below.

A one-compartment, “semi-physiologic” PBPK model was developed by Perkins et al. (49, 50) to describe methanol disposition in mice and rats. Model predictions for methanol disposition in mice during and after inhalation exposure were compared to those previously determined in female Sprague-Dawley rat, and the disposition in mice after various exposure routes was also examined.

Using published kinetic parameters determined after intravenous and oral administration of methanol in humans and other primates, and estimated fraction of absorbed methanol (phi) and physiological parameters, Perkins and colleagues next applied the inhalation pharmacokinetic model for rodents to humans (50). Data for the intravenous exposure were modeled with the one-compartment model described in Perkins et al. (49), with saturable elimination that was first-order at low levels of blood methanol. Data for oral exposure were modeled similarly but with a factor for gut absorption. Maintaining the fraction of absorbed methanol (phi) as the dependent variable, and using kinetic parameters from the oral or intravenous data, inhalation data were then fitted to the previously determined pharmacokinetic model. Background human blood methanol from both endogenous and exogenous sources was set at 1.0 mg/L for the initial time step. The authors estimated that following an eight-hour exposure to 5,000 ppm methanol vapor (6,550mg/m³), blood methanol concentrations in the mouse would be 13-18-fold higher than in humans, whereas methanol concentrations in the rat would be 5-fold higher than the value for humans.
The semi-physiologic model was further applied to methanol disposition in rodents when absorption was confined to the upper respiratory tract, where the majority of methanol absorption occurs (51). Their research results support the hypothesis that absorption of inhaled methanol takes place entirely in the upper respiratory tract of rodents. Methanol absorption was increased by decreased ventilation, but unaffected by increased ventilation. The semi-physiologic pharmacokinetic model developed by the study authors incorporated the body burden of methanol computed from blood methanol measurements, methanol elimination estimates, ventilation rate, and fractional absorption. Because ventilation rate varies with blood methanol concentration, and fractional absorption varies with environmental methanol concentration and ventilation rate, additional equations were derived to modulate these values using nonlinear least-squares regression.

A two-compartment model for methanol disposition in pregnant rodents which utilized Michaelis-Menten elimination from the maternal compartment was developed (48). Pregnant Sprague-Dawley rats were given a single dose of 100 or 2,500 mg/kg/methanol by gavage or intravenously. Pregnant CD-1 mice were also given a single dose of 2,500 mg/kg by gavage or intravenously. Methanol disposition was determined in nonpregnant rats, and at gestation days (gd) 7, 14, and 20 (to approximate three trimesters); in mice, nonpregnant animals and mice at gd 9 and 18 were examined. Blood samples were taken via jugular vein cannula. Rat concentration-time data were modeled using two-compartment models for each dose; mouse data were modeled with a one-compartment model with Michaelis-Menten elimination. Blood methanol levels after oral exposure rose more rapidly in pregnant than nonpregnant rats, but the opposite was true for mice (48). Peak blood levels in rats were higher during pregnancy. \( V_{\max} \) for elimination in near-term rats and mice was 65–80% of that in nonpregnant animals. Mice eliminated methanol twice as fast as rats. Qualitatively, the disposition between pregnant and nonpregnant animals was similar, with the same model, incorporating different parameter estimates, adequately fitting both conditions. In vitro studies showed that adult near-term livers have a \( V_{\max} \) for methanol metabolism of 85% that in livers from nonpregnant rodents. Mouse liver homogenates metabolized methanol twice as fast as rat liver homogenates. Fetal rodent livers had a \( V_{\max} \) less than 5% that of adults.

A PBPK model was developed by Ward et al. (52) for the disposition of methanol in rat and mouse dams and the conceptus (based on the model by O'Flaherty et al. for dimethylxoxazolidine-2,4-dione in pregnant rodents). The model was validated by exposing rats on gd 14 and 20, and mice on gd 18, via injection into the jugular cannula, and using intrauterine microdialysis to measure transplacental methanol toxicokinetics.

The conceptual/maternal diffusion constant ratio consistently decreased with increasing dose in pregnant rats and mice, consistent with earlier observations that methanol limits its own delivery to the conceptus (53). The validated model described methanol elimination as occurring primarily in the liver by a saturable, first-order metabolic process, as has been demonstrated in other studies (34, 42). Methanol tended to partition to tissues with high water content. Peak methanol concentration (\( C_{\max} \)) increased slightly but nonsignificantly in maternal blood as gestation progressed, consistent with the decrease in \( V_{\max} \) for methanol elimination described by Ward and Pollack (48). The conceptual/maternal ratio of AUCs decreased with dose and gestation progression; at low doses conceptual AUC exceeded maternal, but at higher doses, maternal exceeded conceptual AUC. Pregnant mice data from Dorman et al. (54) were also used to validate the model; at 10,000 ppm the conceptual methanol AUC exceeded maternal blood AUC (by 10%), while at 15,000 ppm, the maternal blood methanol AUC exceeded the conceptual AUC (by 30%).
A disadvantage of the microdialysate procedure is the need to keep animals anesthetized. Urethane was used in this study for anesthesia, and it may have had some effect on pharmacokinetic parameters. However, the parameters obtained here fit well with those obtained from other studies with nonanesthetized animals.

The Expert Panel concluded that the studies described above represent an extensive series of carefully conducted experiments to develop pharmacokinetic models for rodents exposed to methanol and to begin to apply the results to humans. The strengths of these are the use of appropriate techniques to measure blood methanol, good study design, and justification of the models. The caveat that needs to be applied is that the exposure levels were high. This can lead to anomalies in absorption. The investigators' own work and that of other groups demonstrate that there are both linear and saturable methanol elimination pathways in rodents whose relative contributions are concentration-dependent. This work has the most utility for understanding rodent toxicity studies. The models need to be validated at lower exposure doses before they can be applied to humans.

Horton et al. (42) developed a two-compartment PBPK model which does not include a fractional absorption parameter (phi). A 4-compartment PBPK model was developed, utilizing a double pathway for metabolism to formaldehyde in the liver: one pathway using rodent catalase K_m and V_max, and one using smaller K_m and V_max values to simulate an enzyme with higher affinity and lower capacity. The compartments were richly perfused tissue (adrenals, brain, gastrointestinal tract), slowly perfused tissue (muscle, fat), kidney, and liver (the major metabolizing compartment). The model was scaled up for humans using the 0.74 power of body weight.

Horton et al. (42) is a careful attempt to develop physiologically-based pharmacokinetic models for methanol in rats, monkeys, and humans. The Horton models differs from those discussed in the preceding section in that they include more compartments but do not account for fractional absorption. Another important difference is that Horton et al. used a much lower range of methanol exposure conditions for the rodent studies, therefore one can have more confidence extrapolating the results to humans. The inclusion of data on primates that was developed in the same laboratory, using the same techniques, is a plus.

Environ (55) performed a comparative analysis of the Perkins et al. and Horton et al. models on behalf of the American Forest & Paper Association (AF&PA). The analysis included the presentation of the exact algebraic forms of the models’ mathematical relationships, and the application of these relationships to the prediction of human, monkey, and rodent blood methanol levels following exposure to low (83 mg/m^3) and higher (260, 1,300, and 2,600 mg/m^3) levels of methanol vapor. Both models produced similar results for steady-state blood methanol levels at various exposures, with the exception of the failure of the Perkins et al. model to achieve steady state at the highest exposure concentration (2,600 mg/m^3) in mice and rats. Because the Perkins et al. model exhibited consistently smaller initial rates of methanol uptake across species, the Horton et al. model predicts higher blood methanol levels prior to achieving steady state. This difference may be due to the fact that the Horton et al. model does not incorporate a fractional absorption parameter (phi). The Perkins et al. model, however, incorporates only a single metabolic compartment, and does not consider lung or kidney elimination, resulting in its inability to reach steady state at high methanol vapor concentrations. Environ (55) concluded that both models support gave a similar predicted result. The Environ (55) analysis also provides additional insights and explanation of the models used in the above studies.

2.2 General Toxicity
The majority of information in this section was obtained from reviews. Because quality reviews have already been conducted, CERHR is basing the general toxicity evaluation on those reviews instead of starting de novo. There were some cases where the primary paper was reviewed, for example newer studies and key papers. The primary reviews utilized in this section were IPCS (1) and Kavet and Nauss (2). The Kavet and Nauss paper is in the main, the published version of an HEI (3) report. Because the Kavet and Nauss paper is more readily available to the public, it is being cited instead of the HEI report.

2.2.1 Human Data
Laboratory Studies

Two controlled studies examined the neurotoxic effects associated with methanol inhalation in humans and were evaluated by the Expert Panel.

Cook et al. (21) conducted a pilot study to obtain information about effects of acute methanol exposure on neurobehavioral function and methanol and formate levels in blood. Twelve healthy young men (22–32 years of age) were trained on tests for neurobehavioral function. They were then randomly exposed to air or methanol at 250 mg/m$^3$ (191 ppm) for 75 minutes in a double blind study. Each subject served as his own control and was exposed twice to both methanol and air at the same time of the morning. For twelve hours prior to exposure, the subjects were instructed to eliminate alcohol, diet foods and drinks, fruit and fruit juices, and coffee from their diets. The methanol exposures resulted in an increase in blood methanol but not blood formate levels, as discussed in Section 2.1.1.1. Subjects were tested for a battery of neurobehavioral endpoints that are widely used to identify effects of environmental pollutant exposure. Statistically significant effects and trends were found for brain wave patterns in response to light flashes and sounds (P-200 and N1-P2 component of event-related potentials), performance on the Sternberg memory task, and subjective measures of fatigue and concentration. The study authors noted that effects were mild and did not exceed normal ranges. However, they noted some limitations in their study such as a small sample size, use of only one exposure concentration and duration, and an inability to completely mask the odor of methanol from subjects and experimenters. The authors recommended that steps be taken to eliminate those limitations in future studies.

Strengths/Weaknesses: There are a number of experimental design strengths in this study. These include: the use of each subject as his own control, random assignment to exposure in order to control for potential order effects, double-blinding to exposure condition, monitoring of blood methanol and formate levels, multiple neurobehavioral testing consisting of validated outcome measures that pertain to everyday tasks, careful attention to calibration of instruments, and strict statistical design of study protocol and data analysis to take repeated measurements and multiple comparisons into account. Although the sample size was small (n=12), the selection of sample size was based on consideration of statistical power (to the extent possible).

The design also imposes limitations on the interpretation of results. Notable are the single dose design that precluded assessment of potential dose response and the short duration of exposure (75 minutes). Another possible weakness is an apparent failure to completely blind subjects to exposure condition. However, subjects who were most accurate at guessing condition did not necessarily demonstrate the greatest exposure-related changes in test scores, suggesting that their hunches did not affect their performance.

The Expert Panel reviewers noted that although the authors concluded that the results were essentially negative, the differences seen all tended to be in the direction favoring the control
condition over the methanol condition (self-ratings of vigor, concentration, and fatigue; reaction
time, slope and intercept measures on the Sternberg memory task; P200 latency and N1-P2
interval on the auditory event-related potential task). Moreover, the results of the regression
analyses indicated that chamber methanol concentration, blood methanol concentration post
exposure, and blood methanol change contributed to the prediction of a variety of test scores. As
the authors recognized, if more than one methanol concentration, or more than one exposure
duration had been included in the experimental design, “meaningful dose-relationships might be
found even at levels of methanol exposure expected as a result of its use as a motor fuel” (p.25 of
the Cook study). The P-values associated with some of the trends reported might have reached
statistical significance if sample size were only modestly increased. The authors minimized the
importance of the neurobehavioral effects seen, noting that they were still “within the normal
range”. While perhaps true, this does not necessarily mean that effects with more serious
implications for daily life were not also present but not assessed by the test battery. As the
authors suggest, the use of more difficult tasks, such as those that model more closely complex,
demanding behaviors such as driving, might reveal larger methanol-associated changes in
performance.

Utility (adequacy) for CERHR evaluation process: The use of a young, healthy population
limits the utility of this study. The generalizability of the findings might be limited as other
populations such as the elderly, children, individuals with lung disease, could potentially be more
susceptible to methanol effects than are healthy young males. However, this well-designed and
conducted study strongly suggests that short-term exposure (75-minute) to methanol at a
concentration of 250 mg/m³ might be associated with a variety of adverse neurobehavioral
changes. Although effects on P300 and the Sternberg test were weak, the confidence of these
finding is increased by similar observations at similar exposure levels as Chuwers et al. The
study raises the possibility of more serious findings or effects at lower exposure level in possibly
sensitive subpopulations. Although the study is of limited use for deriving dose-response
relationships between methanol exposure and neurobehavioral test performance, the effects at 250
mg/m³ suggest either a free standing NOAEL or LOAEL for minimal effects close to a NOAEL.
The study provides many useful suggestions about future directions for research.

Chuwers et al. (22) also studied the neurotoxic effects of acute methanol inhalation in human
subjects exposed to the occupational threshold limit value of 200 ppm for 4 hours. In a
randomized double-blind study design, 15 men and 11 women (healthy, aged 26–51 years) served
as their own controls and were exposed once each to water or methanol vapors for 4 hours.
Subjects were trained on neurobehavioral tests prior to exposures. The exposures were conducted
at the same time of the morning and were separated by 4 weeks in women. Subjects were
instructed to eliminate coffee, vegetables, fruit or fruit juices, fermented drinks, and aspartame
from their diet for 24 hours prior to exposure. In addition, they were told not to take Vitamin C
for 3 days prior to exposure because it interferes with folate measurements. Exposures increased
blood and urine concentrations of methanol but not formate, as discussed under Osterloh et al.
(28) in Section 2.1.1.1. There were no significant effects on visual, neurophysiological, and
neurobehavioral endpoints, with the exception of some between-subject variables. Slight effects
on P-300 amplitude (brain waves in response to sensory stimuli) and Symbol Digit testing
(information processing and psychomotor skills) were noted. Between subject variables for P-
300 included alcohol consumption and smoking and the between subject variable in the symbol
digit test was age. Double blinding was not completely effective because some experimenters
and subjects were able to correctly guess when the methanol exposures occurred. The study
authors concluded that methanol exposure at this concentration had little effect on
neurobehavioral performance.
**Strengths/Weaknesses:** In many respects, this is a very strong study methodologically with strict statistical design. Although the subjects were a convenience sample, care was taken to eliminate individuals with potentially confounding conditions such as liver or CNS (e.g., visual) disorders. The design included using subjects as their own controls (pre-testing and post-testing within both methanol and control exposure conditions), randomizing the order of exposure to methanol and control (double-blind), providing training on the neurobehavioral tests to reduce learning effects and anxiety, administering the tests at the same hour each day and, 4 week separation of testing in women to reduce hormonal effects. The selection of the neurobehavioral tests included in the battery was based on prior literature on solvent exposures. A number of sensitive neurobiological endpoints were examined, and the endpoints were sensitive to the types of findings expected from environmental exposure. For the most part, the tests are well standardized and appropriate for repeated administration over short periods of time. Good quality control procedures were implemented for both biological and neurobehavioral measurements.

The study has some important weaknesses, however. First, the sample size was small, so that the statistical power of hypothesis testing was adequate only for detecting rather substantial differences (0.8 standard deviations). It might not be reasonable to expect that exposure to methanol at the concentrations used would have effects of this magnitude. In fact, only slight effects were noted on P300 and symbol digit testing with the performance of multiple tests. Second, despite the QA/QC procedures, a surprising amount of data had to be discarded because of apparent experimenter error (Symbol-Digit) or technical problem (7 of 26 P-300 waveforms unacceptable, 5% contamination of serum methanol levels). Third, blinding apparently failed insofar as the primary investigator was correct 100% of the time in guessing whether an exposure was methanol or control. Subjects correctly identified exposure conditions 18 of 26 times. This could easily have affected subjects’ test performance. Fourth, the manner in which the statistical analyses are reported is confusing, making it difficult to understand exactly what the findings were. The authors suggest that factors such as alcohol use, smoking, and folate status might alter susceptibility, although it is not clear whether the appropriate interaction terms for testing such hypotheses were included in the regression analyses. It appears that they were included as main effect terms, which would not address the issue of effect modification. The study would have had very low power to evaluate this.

Utility (adequacy) for CERHR evaluation process: This study essentially found that if 4 hours of exposure to a methanol concentration of 200 ppm has effects on neurobehavioral functioning, the effects are likely to be smaller than a 0.8 standard deviation in magnitude. The study is uninformative on the issue of whether or not this is actually the case. However, this is a well-designed study with double blinding and exposed subjects serving as their own controls; therefore we have high confidence. It has a strict statistical design and examines a number of relevant neurobehavioral endpoints that are sensitive to the types of findings expected from environmental exposure. It has limited ability to draw conclusions relevant to reproductive effects. As the LOAEL observed is for very mild effects it is likely very close to a no effects level. The confidence is strengthened by similar findings in Cook et al. (21) study. The single acute exposure design is not relevant for chronic exposure to the general public. Results from a single dose in healthy young adults may not predict effects in sensitive populations.
Kavet and Nauss (2) reviewed Russian studies by Chao and Ubaydullayev that reported effects in visual, olfactory, and reflex thresholds in humans following exposure to <9 ppm methanol vapors. However, Kavet and Nauss noted limitations such as inadequate reporting of details and the fact that some of the effects occurred at levels that would not impact background levels of methanol.

**General Population Case Studies**

Information on methanol toxicity in the general population is available for acute and repeated exposure. The information provides no insight on effects to the reproductive system. This summary of general population effects is based on reviews by Kavet and Nauss (2) and IPCS (1).

Case studies describing effects of acute methanol exposure in humans date back to the early 1900’s. The majority of human methanol poisonings have resulted from consumption of adulterated alcohol beverages (1). However, acute methanol toxicity has been noted in adults and children following percutaneous or inhalation exposures, and symptoms have been equivalent to those observed with oral exposure. The progression of methanol-induced toxicity in humans has been well characterized in reviews by Kavet and Nauss (2) and IPCS (1). The first symptom of acute methanol poisoning is a transient, mild central nervous system depression that is followed by an asymptomatic period lasting from hours to days. After the asymptomatic period, metabolic acidosis develops in parallel with toxicity to the eye. Symptoms during this time period include headache, dizziness, nausea, and vomiting. Visual symptoms may include blurred vision, altered visual fields, impaired pupil response to light, and permanent or temporary blindness. In patients with visual toxicity, examination by ophthalmoscope may initially reveal hyperemia of the optic disc followed by the development of peripapillary edema. Edema, which may persist for up to 2 months, occurs along the major blood vessels and seems to be found primarily in the nerve fiber layer of the retina. Optic disc pallor may occur 1–2 months after poisoning and is a sign of irreversible eye damage.

In severe cases of acute methanol poisoning, abdominal pain and difficulty breathing, may occur and progress to coma and death, usually from respiratory distress (1, 2). Autopsies conducted on victims of methanol poisoning revealed gross pathological effects consisting of edematous, hemorrhagic, and degenerative changes in visceral organs, liver, kidneys, lungs, and central nervous system (CNS). The part of the brain most affected by methanol poisoning is the basal ganglia, especially the putamen. Survivors of severe methanol intoxication may suffer from motor disorders associated with damage to the putamen. It has been reported that 300–1,000 mg/kg bw methanol is the minimum lethal dose in untreated victims. Blood levels ≥0.5 mg/ml may be obtained after ingestion of 0.4 ml/kg body weight (bw) and patients with that blood level generally require treatment by hemodialysis. However, doses producing toxicity, the types of symptoms developing, and the time course of symptom development vary widely among members of the population. Sensitivity to methanol poisoning may be affected by concurrent ingestion of ethanol which may increase the latency period. Inadequate dietary folate intake may result in compromised metabolism and increased sensitivity to methanol.

Use of methanol in gasoline is a potential source of acute methanol exposure and data on accidental ingestion of gasoline is discussed in Section 1.2.4.

Kavet and Nauss (2) describe case studies involving repeated exposure to methanol. Most case studies provide no information about levels and duration of exposure. However, they do
demonstrate effects that are consistent with acute intake such as visual toxicity, headache, and vomiting. Those symptoms were noted after inhalation, oral, and dermal exposure.

**Occupational Epidemiological Studies**

A series of epidemiological studies addressed methanol exposure in occupational settings. Four studies were reviewed by both IPCS (1) and Kavet and Nauss (2). The studies were also reviewed by CERHR to verify the information reported in Kavet and Nauss and IPCS. A study by Frederick et al. (56) of NIOSH was considered by Kavet and Nauss to be the most definitive. In that study, headaches, dizziness, blurred vision, and nausea/upset stomach were reported by teacher aids working near spirit duplicators using a 99% methanol fluid for 1 hour/day for 1 day/week or 8 hours/day for 5 days/week over a period of 3 years. Methanol levels in air ranged from 365–3,080 ppm. A study by Kingsley and Hirsch (57) reported headaches in clerical personnel working near duplicating equipment using methanol-based fluids. Methanol air levels near the equipment were measured at up to 375 ppm. In a second study by NIOSH (58) it was reported that 45% of spirit duplicating machine operators at the University of Washington experienced symptoms such as blurred vision, headache, nausea, dizziness, and eye irritation; the average methanol concentration in the area was measured at 1,025 ppm. Greenberg et al. (59) reported no visual or CNS symptoms in 19 workers manufacturing fused collars who were exposed to 22–25 ppm methanol vapors from 9 months to 2 years.

A study by Kawai et al. (60) examined subjective complaints and clinical findings in workers exposed to methanol for 0.3–7.8 years and utilized methanol in urine as a biological indicator of exposure. Regression analysis estimated that an 8-hour exposure to 200 ppm methanol would result in a mean urinary methanol level of 42 mg/L. The most common complaints in workers exposed to a mean methanol concentration of 459 ppm included nasal irritation, headache, forgetfulness, and increased skin sensitivity. A complaint of dimmed vision was found to be due to methanol vapors in air and not retinal toxicity. In 3 workers exposed to 953–1,626, 1,058–1,585, and 119–3,577 ppm methanol, pupil response to light was slow in 2 workers and a third worker had dilated pupils. However, the optic disc was unaffected and there was no indication of permanent eye damage.

### 2.2.2 Animal Data

Studies examining methanol-induced toxicity in animals following acute and repeat dose toxicity are available. The majority of the acute studies provide no insight on methanol-induced toxicity to the reproductive system. Therefore, most of the information about methanol induced systemic toxicity was summarized from reviews by Kavet and Nauss (2) and IPCS (1).

Acute toxicity has been examined in rats, mice, rabbits, dogs, and monkeys. Kavet and Nauss (2) discussed the relevancy of different animal models for evaluating acute methanol toxicity in humans. They noted that the majority of laboratory animals do not develop acidosis and visual toxicity as noted in human methanol poisonings. Kavet and Nauss discuss a landmark paper published in 1955 by Gilger and Potts that established the non-human primate as the model of choice for evaluation of acute toxicity. In the Gilger and Potts paper (61), oral acute methanol toxicity was examined in rats, rabbits, dogs and rhesus macaque monkeys. The two main findings of Gilger and Potts were: (1) the lethal dose in non-primates was 2–3 times higher than the 3,000 mg/kg bw lethal dose reported for monkeys and 6–10 times higher than lethal doses reported for humans (Table 2-7), and (2) only the non-human primates experienced symptoms similar to humans: intoxication, a 1-day latency period and then development of acidosis with some ocular toxicity prior to death. In the non-primates, acidosis did not develop and symptoms...
consisted of narcosis that was sometimes followed by death. Kavet and Nauss concluded that the legitimacy of the non-human primate has been confirmed but also stated that “...non-primates may remain appropriate models in studies that seek to understand the direct alcoholic effects of methanol.”

Additional studies of acute toxicity in primate and non-primate species were reviewed by IPCS (1) and the results following oral or inhalation dosing were consistent with those described by Kavet and Nauss (2). IPCS also reviewed a study by Dorman et al. (62) that reported intoxication, but a lack of optic nerve lesions, formate accumulation, and metabolic acidosis in minipigs gavaged with a single dose of methanol up to 5,000 mg/kg bw. The Expert Panel noted that the histological examination by Dorman et al. did not include reproductive organs.

An acute study by Youssef et al. (63) was reviewed by the Expert Panel because it examined neurobehavioral toxicity, an effect evaluated in some developmental toxicity studies. The study was designed to examine methanol-induced effects at levels that do not produce overt toxicity. The study used rats, a model considered appropriate by authors because formate levels in humans are not elevated at low to moderate doses of methanol. Eleven adult [age not specified] male Crl: Long-Evans rats served as their own controls and were gavaged with water and 1,000, 2,000, and 3,000 mg/kg bw methanol in water (50% solution) on different days. HPLC-grade methanol was used, which has a purity of 99.93% (Aldrich 2000–2001). The doses represented 10, 20, and 30% of the methanol LD50. The experiment was conducted twice at each dose. Ten minutes after dosing, the animals were subjected to the fixed wheel running ratio test to assess operant running. The test required the animal to run inside a wheel and rotate it under a fixed ratio of 20 times (FR20) in order to receive a food reward. Data were evaluated by conducting repeated measures analysis of variance (ANOVA), determining linear trend, correcting for degrees of freedom, and performing analysis of residuals to identify outliers and skewed distribution. The rats displayed no signs of overt intoxication such as gait disturbance, but a significant, dose-related reduction in FR20 response was observed with methanol treatment.

**Strengths/Weaknesses:** The study by Youssef et al. (63) has many strengths. Chemical grade of methanol was reported. The doses were not expected to form significant formate levels in rats and dose-response relationships were identified. The operant-running test is very sensitive to alterations in complex motor performance and is able to identify responses in a more sensitive manner than observational studies. Another strength of this study was that a stable baseline, within-subject approach was used, generating great confidence in the dose effects.

Weaknesses include the use of 50% methanol by gavage, clearly an irritating dose, and the lack of a control for the volume of the highest dose. In addition, methanol concentrations in dosing solutions were not verified. A minor weakness was the failure to test even higher doses, as the
statistics did not indicate whether the highest dose would have resulted in a statistically significant effect alone (i.e., what was the LOAEL?).

Utility (adequacy) for CERHR evaluation process: This study demonstrated a monotonic dose-effect relationship, with about a 40% decrease in responding with the highest dose of methanol. The study contributes to our discussion in that it is one of the few to produce clear dose-related effects. It also contributes to the discussion of whether 'other' (CNS?) effects should be included in risk assessments for methanol exposure. The panel believes the study is valuable because it identifies a relevant endpoint in a particularly sensitive fashion. It indicates that effects occur at exposures below those identified in observational studies. However, despite the sensitivity of testing methods used, studies correlating the relationship of the test protocol to human function are needed. While it’s relevance to reproductive consequences is in question, it does indicate the need to use sensitive neurobehavioral testing during times of rapid brain growth and integration (in fetal and postnatal exposures) and in chronic exposure scenarios. The article also included an interesting analysis in the attempt to determine whether methanol’s effects on behavior were motivational or motoric. This issue continues to plague behavioral research, but is not germane to the discussion. One limitation to utility was that the study only provided information about acute exposures and doses were greater than those expected from environmental exposure. In addition only adult males were examined and a NOAEL was not identified. Confidence is moderate with the limitations noted.

Numerous repeat dose studies were reviewed by Kavet and Nauss (2) and IPCS (1). The majority of those studies provided no information on effects to reproductive organs or other endpoints of interest, but did identify the primary organs affected by methanol exposure. Studies in rats, dogs, and rabbits primarily noted toxicity to the eye, brain, and liver. Russian studies by Chao (2) and Ubaydullayev (2) reported changes in chronaxy ratio (minimum time for a stimulus twice the intensity of the absolute threshold to induce a response) following exposure of rats to 38 ppm methanol vapors for 90 days. Kavet and Nauss concluded that the studies do not provide sufficient evidence of an association between low-level methanol exposure and neurobehavioral effects in rats due to limitations such as inadequate reporting of details and unknown biological significance.

Kavet and Nauss (2) and IPCS (1) reviewed methanol toxicity studies by the Japanese New Energy Development Organization (NEDO). In a study to evaluate non-carcinogenic effects, 20 Fischer-344 rats/sex/group and 30 B6C3F1 mice/sex/group were exposed to 10, 100, or 1,000 ppm methanol vapors for 2 hours/day for 12 months. Mild effects were only observed at the highest dose for rats and mice. Effects in rats included reduced weight gain in males and females and a non-significant increase in relative liver and spleen weight in females. In mice bodyweights were increased in males at 6 months and females at 9 months and fatty degeneration of hepatocytes was enhanced. Clinical analysis resulted in no treatment related effects. Kavet and Nauss noted that a critical review of the NEDO studies and results was not possible because the reports did not contain sufficient amounts of technical data and histopathological results.

One recent study provided information about sensitivity in folate-reduced rats, and a limited number of studies included a histological examination of the reproductive system. Those studies were reviewed by the Expert Panel and are discussed below. Because methanol has been proposed for use as an additive in gasoline, some studies have been conducted to examine the toxicity of gasoline/methanol blends. This document will only focus on studies that provide information on the toxicity of methanol alone or on the interaction between methanol and gasoline.
Lee et al. (39), in a series of experiments, demonstrated that the toxic response to methanol in rats on a folate reduced diet included death, elevated blood formate and metabolic acidosis after exposure to 3,000 ppm of methanol vapor. These effects were similar to those reported in the literature for non-human primates. The details of this study are presented in Section 2.1.3.

Andrews et al. (64) conducted a subchronic inhalation study in rats. Five male and female Crl:CD (Sprague-Dawley) rats/group (50 days old) were exposed to methanol vapors (99.85% purity) at 0, 500, 2,000, and 5,000 ppm for 6 hours/day, 5 days/week for 4 weeks. [The rational for dose selection was not discussed.] Controls were exposed to house-supply air only. Statistical evaluation of data is discussed below in the synopses of the primate study conducted by Andrews and Terrill (1987). The only clinical sign observed was nasal and ocular discharge in methanol-treated rats. Weekly measurement of body weight revealed no differences between control and treated animals. At necropsy, organ weights were measured and the organs assessed included testes, epididymides, and ovaries, apparently in all animals. Relative spleen weight was significantly increased in female rats exposed to 2,000 ppm methanol, but the study authors did not consider the effect to be of biological significance. Thyroids were not examined histologically and it is not certain if a histopathological examination of reproductive tissues was conducted. The authors stated that testes, epididymides, and eyes were among the tissues preserved in Bouin’s solution for microscopic examination. However, of those 3 organs, only the eye from control and high-dose animals was said to be prepared in slides and examined microscopically. Gross and histopathological examination revealed no effects in organs examined. No ocular abnormalities were noted in an ophthalmoscopic exam. The study authors concluded that the study identified no target organs of effect.

Strengths/Weaknesses: See summary under the discussion of primate effects later in chapter.

Utility (adequacy) for CERHR evaluation process: See summary under the discussion of primate effects later in chapter.

Poon et al. (65) studied the toxicity associated with methanol exposure alone or in combination with toluene, a component of gasoline. Groups of 10 Crl:Sprague Dawley rats/sex/group (~4 weeks old) were exposed to filtered room air or vapors of methanol (300 or 3,000 ppm), toluene (30 or 300 ppm), or methanol/toluene (300/30, 300/300, 3,000/30 or 3,000/300 ppm) for 6 hours/day, 5 days/week, for 4 weeks. Purity of both methanol and toluene was >99.7%. [No rational for dose selection was provided.] Ten animals/dose/sex were evaluated in all methanol containing groups at the end of exposure old. Statistical significance was determined by one-way ANOVA and Duncan’s range test. Methanol treatment alone did not result in clinical signs of toxicity, reduced growth rate, or effects on serum chemistry or hematology. A limited number of organs were weighed at necropsy, but not the reproductive organs. Methanol exposure alone had no effect on organ weights. The pituitary gland and reproductive organs were among the organs fixed in 10% buffered formalin and examined histologically in 5–6 animals/group/sex. However, effects on reproductive organs were not reported. The authors stated that a mild to moderate reduction in thyroid follicle size was noted in female rats treated with both doses of methanol only. Although the authors stated in the text that thyroid changes in males were not as apparent, the tables reported a higher incidence and greater severity of thyroid effects in control males and males exposed to methanol. Mild histological effects in nasal passages were noted for both males and females exposed to both dose levels of methanol. The incidence of nasal lesions was increased in rats exposed to mixtures of methanol and toluene compared to exposure to either compound alone. Other effects noted in rats exposed to toluene or methanol/toluene mixtures
included mild thyroid and liver effects. The authors concluded that “there were no apparent interactive effects observed.”

**Strengths/Weaknesses:** The strengths of this study included use of a large study population (100 animals, 10/sex/group) that was randomly assigned to exposure groups, evaluation of blood chemistry and liver P450 level, reporting of the methanol purity, monitoring of chamber methanol concentrations, and considerations of interactive effects with toluene. A limitation of study design was that histopathological evaluation was only conducted in about half the animals.

**Utility (adequacy) for CERHR evaluation process:** This study raises the question of thyroid as a possible target organ for methanol. However the Expert Panel concluded that thyroid findings were questionable. They noted that control males experienced a reduction in follicle size. No substantial or consistent thyroid findings were noted in this study and the thyroid findings were not confirmed by Poon (66) (discussed below). The thyroid findings were mild and half of the animals were not examined histopathologically, resulting in examination of small numbers. The nasal respiratory findings require careful consideration due to anatomic differences between rats and humans and because rats are obligate nose breathers. No significant toxicological effects were identified by this study. No information is given regarding possible structural or functional findings in the reproductive organs. It is of limited utility in evaluating reproductive hazards.

Poon et al. (66) studied the toxicity associated with exposure to methanol, gasoline, and methanol/gasoline blends. Groups of 15 Crl: Sprague Dawley rats/sex/group (4–5 weeks old) were exposed to filtered room air or vapors of 2,500 ppm methanol, 3,200 ppm gasoline, 2,500/3,200 ppm methanol/gasoline, or 570/3,200 ppm methanol/gasoline for 6 hours/day, 5 days/week, for 4 weeks. Methanol purity was >99%. [The rational for dose selection was not provided.] Effects were evaluated in 10 rats/sex/group. Statistical significance was evaluated by one-way analysis of variance and Duncan’s multiple range test. No clinical signs were observed and methanol had no effect on body weight gain. Mild histological changes were noted in nasal passages following exposure to methanol. A lack of significant changes in protein concentrations and enzyme activities in bronchoalveolar lavage fluid indicated that lung injury did not occur with methanol exposure. Serum chemistry and hematological analyses were conducted and the only effect noted was a significant decrease in serum sodium levels in females treated with methanol. At necropsy it was noted that 2 males exposed to methanol had collapsed left eyes. Measurement of organ weights included the left testis weight in which effects were not observed. A significant decrease in relative spleen weight was noted in the methanol-exposed females. Histopathological examination included reproductive organs, the pituitary, and thyroid preserved in 10% buffered formalin. The only histological effect noted was mild hepatic panlobular vacuolation in females exposed to methanol. It is interesting to note that this study failed to replicate the thyroid effects seen in an earlier study by Poon et al. (65). Effects noted with exposure to gasoline or methanol/gasoline mixtures included decreased bodyweight gain, liver effects, reduced hemoglobin levels, and suppressed uterine eosinophilia. The study authors concluded that there were “no apparent interactive effects between methanol and gasoline.”

**Strengths/Weaknesses:** The strengths of this study included a large study population (15/sex/group) that was randomly assigned to exposure groups, gross and histopathological examination of male and female reproductive organs, reporting of methanol purity, control of and reporting of chamber conditions (i.e., vapor concentrations), and broad-spectrum of measures such as serum chemistry and hepatic enzyme activity.
Some weaknesses were noted from the point of view of a reproduction assessment. For example, there was limited measurement of reproductive organ weights. Also, the testis and ovary were inappropriately fixed and stained, thus reducing the confidence that the authors would be able to find the inhibited spermatiation lesion characteristic of reduced testosterone levels. Additionally, formalin fixation prior to paraffin embedment makes for greater variability in the quality of testis sections. That means that subtle changes in cell associations (which could portend larger changes with further exposure) could easily be overwhelmed by shrinkage artifact. Lastly, there was no evaluation of female reproductive cycling, and no ovarian morphometry. Therefore, there is no information about any change in follicle dynamics that underly female fertility.

Utility (adequacy) for CERHR evaluation process: This well-designed study demonstrated no significant findings attributable to the methanol components nor an interactive effect with gasoline. It would appear that the minimal nasal histological changes at 2500 ppm represent a finding close to a NOAEL for this endpoint. However, as discussed previously, rat nasal findings require careful interpretation. There is a high level of confidence for this study within the limits noted above. The Panels notes that uterine histopathology was specifically reported and the study demonstrated no myometrial eosinophilic changes attributed to methanol exposure alone. However, the Panel found these studies of modest utility in assuring a lack of methanol effect on rodent reproduction. The Panel is confident that the authors would have found major lesions or massive cell loss from the gonads and associated reproductive tissues due to methanol exposure had they occurred. The Panel was less confident in the ability of these methods to accurately identify and characterize modest lesions in reproductive organs.

The utility of the general toxicity data set would improve if a chronic exposure study was available.

Andrews et al. (64) conducted a subchronic inhalation study in monkeys. Three male and 3 female Cynomolagus (Macaca fascicularis) monkeys/group (from Primate Imports, age not specified) were exposed to house-supply air or methanol vapors (99.85% purity) at 500, 2,000, and 5,000 ppm for 6 hours/day, 5 days/week for 4 weeks. [The rational for dose selection was not discussed.] Body and organ weight data were first analyzed by Barlett’s test and if variances were equal, parametric procedures were used (one-way ANOVA). Non-parametric procedures (Kruskal-Wallis test and summed-rank test) were applied if variances were not equal. Dose-trend tests were also conducted. Weekly measurement of body weight revealed no differences between control and treated animals. At necropsy, organ weights were measured and the organs assessed included testes, epididymides, and ovaries. Absolute adrenal weight was significantly decreased in female monkeys of the 5,000 ppm group, but the effect was not considered to be of biological significance by authors. Thyroids were not examined histologically and it is not certain if a histopathological examination of reproductive tissues was conducted. The authors stated that testes, epididymides, and eyes were among the tissues preserved in Bouin’s solution for microscopic examination. However, of those 3 organs, only the eye from control and high-dose animals was said to be prepared in slides and examined microscopically. Gross and histopathological examination revealed no effects in organs examined. No ocular abnormalities were noted in an ophthalmoscopic exam. The study authors concluded that the study identified no target organs of effect.

Strengths/Weaknesses: The strengths of the Andrews et al. (64) study in rats (discussed above) and monkeys included the examination of repeated exposures via inhalation (few other studies looked at this presumed common environmental pathway). The range of exposures were large
(0–5,000 ppm), the purity of methanol was noted, and chamber concentrations of methanol were verified and reported. Lastly both rats and monkeys were used (rat study described above).

Limitations in study design included no report of histopathological evaluation of reproductive organs, small group sizes (n=5 rats/sex/group and 3 monkeys/sex/group), a lack of hematological and blood chemistry analysis, and no measurement of formate levels. The authors did not state if assignment to exposure groups was random.

The Expert Panel notes one questionable finding. Female monkeys had a statistically significant decrease in adrenal weights and an increase in splenic weights. These findings are discounted by the authors as “not of biologic significance.”

**Utility (adequacy) for CERHR evaluation process:** This study is of limited utility to CERHR process as specific mention of pathological examination of reproductive organs is missing. Small number of non-human primates limits statistical significance.

### 2.3 Genetic Toxicity

Because the IPCS (1) already conducted a thorough review of genetic toxicity information, the Expert Panel summarized the main findings of the review in Tables 2-8 and 2-9. The majority of findings were negative but some positive results were obtained. The IPCS stated that “The structure of methanol (by analogy with ethanol) does not suggest that it would be genotoxic.”

IPCS (1) also reported negative findings in the Ames test, somatic mutation assay in CH-V79 cells, chromosome aberrations, SCEs and the micronucleus test performed by NEDO.

The following study was not included in the IPCS review:

Fu et al. (67) examined micronuclei formation in reticulocytes of pregnant CD-1 mice fed diets with adequate or marginal levels of folic acid (1,200 nmol and 400 nmol/kg, respectively) and gavaged with methanol in water at 0 or 5,000 mg/kg bw/day on gd 6–10. Neither methanol nor reduced folic acid intake increased the frequency of micronuclei formation. Additional details of this study are included under Section 3.2.3.

2.4 Carcinogenicity

Kavet and Nauss (2) and IPCS (1) reviewed methanol studies by the Japanese New Energy Development Organization (NEDO). Rats and mice were exposed to 10, 100, or 1,000 ppm methanol vapors for 20 hours/day for 24 and 18 months, respectively. A non-statistically significant increased incidence of papillary adenomas and adrenal pheochromocytomas were observed at the highest dose, but NEDO concluded that there was no evidence of cancer. NEDO also exposed 8 female Macaca fascicularis monkeys/group to 10, 100, or 1,000 ppm methanol vapors for 22 hours/day for up to 29 months and reported a non-dose- and time-related hyperplasia of “reactive astrocytes” in the nervous system. Methanol exposure had no effect on bodyweight or hematological or pathological parameters. Kavet and Nauss (2) noted that a critical review of the NEDO studies and results was not possible because the reports did not contain sufficient amounts of technical data and histopathological results.

2.5 Summary of General Toxicological and Biological Parameters

Toxicokinetics

Methanol is not foreign to the bodies of mammals including man as it occurs naturally as a product of endogenous biochemical processes. As described in Section 1 methanol is consumed as a natural part of the human diet and is also found in different aspartame-sweetened and fermented beverages. Thus, methanol is present in human blood; background blood levels are somewhat variable and may range from 0.6 (21) to 1.8 mg/L (24, 28). At least one study has reported higher baseline blood levels of methanol in females than males (25).

The absorption, distribution, metabolism and excretion of methanol are generally understood in humans, monkeys, rats, and mice (1, 2). There are sufficient data from human studies and those of other species to demonstrate rapid absorption following exposure by inhalation, dermal and oral routes. Following absorption, methanol distributes rapidly and uniformly to all organs and tissues in direct relation to their water content. Methanol elimination, in expired air and urine, are somewhat proportional to methanol concentration in blood, but account for a minor portion, 3.1%, of the dose at concentrations that do not saturate metabolic pathways. At saturating doses these routes may become more significant (34).

In mammals methanol is eliminated primarily by metabolism through a series of oxidation steps to sequentially form formaldehyde, formate and carbon dioxide. At high methanol doses, increased formate concentration and resulting acidosis is thought to account for most of the toxicity (1). While metabolism of methanol to formaldehyde utilizes different enzymatic pathways this step occurs at similar rates in primates and rodents (1). Formaldehyde is rapidly oxidized (half-life of ~1 minute) to formate in all species. It is the rate at which formate is oxidized to CO₂ that accounts for the pronounced species difference in the toxicity of methanol. In rodents the catalase-peroxide system and enzymes utilizing folate as a co-enzyme provide considerable capacity to catalyze this reaction whereas primates depend heavily on the pathway involving folate. Since primates appear to have less catalase and naturally have lower folate concentrations than do rodents they have considerably less capacity to metabolize methanol. Formate is oxidized to CO₂ in rodents at twice the rate seen in primates. As a result, the rate of formate oxidation in rats exceeds the maximal rate at which methanol is converted to formate - 1.6 vs. 0.9 mmol/kg/hr, respectively (2). In contrast, when primates receive moderately high doses of methanol the formation of formate can exceed the oxidation of formate - ~1.5 vs. 0.75
mmol/kg/hr, respectively. The net result is that primates may accumulate levels of formate that exert toxicological consequences at doses far lower than those needed to produce equivalent effects in rodents. A calculated estimate of the methanol concentration that saturates the human folate pathway is 11 mM or 210 mg/kg (2). It is this species-specific difference in formate metabolism that greatly confounds use of laboratory rodent data to predict human health risks associated with exposure to methanol. It should be noted, however, that whereas exposure of healthy humans to up to 800 ppm for varying periods of time demonstrated time and concentration dependent increases in blood methanol, increases in blood formate were not detected. The literature indicates that human toxicity most frequently results from bolus doses associated with accidental or intentional ingestion that overwhelms the capacity for metabolism of formate to carbon dioxide. There is no information on the effects of chronic exposure on toxicokinetics in humans. Information from non-human primates (41) indicates that long-term exposure (exposure each day for ~300 days) resulted in an increase in methanol clearance rates with no increase in blood formate at exposure levels up to 1,800 ppm. From these data it is reasonable to conclude that inhalation of methanol at doses up to 1,800 ppm is unlikely to result in elevated blood formate levels in healthy humans. However, there are no toxicokinetic data on humans with marginal folate tissue concentrations. There are limited data to indicate that a single two-hour exposure of folate deficient non-human primates to 900 ppm methanol vapor did not increase blood formate levels (44).

Whereas the disposition and metabolism of methanol appears to be similar regardless of the route of administration (oral, dermal or inhaled), retention of inhaled doses appears to be inverse to the size of the animal. With inhalation of high doses of methanol the rate of accumulation in the mouse was two to three-fold greater than observed for rats possibly due to a higher respiration rate and more complete absorption in the nasal cavity. Rats retain a significantly greater portion of the inhaled dose than do humans. The fate of methanol in pregnant animals has been subject to less research than the toxicokinetics of methanol toxicity. Available data indicate little or no difference in methanol toxicokinetics as a function of pregnancy in non-human primates (41). In pregnant mice there was an indication that penetration of methanol to the fetal compartment decreased in inverse proportion to higher dose, possibly as a result of decreased blood flow (34). Pollack and Brouwer did report a statistically significant decrease in V_max for formaldehyde formation in rat and mouse liver homogenate, a finding they described as relatively minor.

Finally, it is to be noted that several models have been developed for the use of methanol data (34, 49, 50). These models are of value in better understanding the dose and metabolite effects of methanol administered at high dose studies in rats and mice. They remain unvalidated for the extrapolation of dose effects to levels associated with current or anticipated exposures of the general and worker population. The Horton et al. (42) model is a careful attempt to develop physiologically-based pharmacokinetic models for methanol in rats, monkeys, and humans. The authors used a much lower range of methanol exposure conditions for the rodent studies, which increases confidence in extrapolating results to humans. The panel notes that Environ (55) performed a comparative analysis of the Perkins et al. (50) and Horton et al. (42) models that provides insights as to the model features and differences.

The toxicokinetic data pertaining to methanol are of sufficient breadth, depth and quality to contribute in a material way to evaluating the potential for methanol to pose a risk to human reproduction.
General Toxicity

The primary sources of information used by the Panel on the general toxicity of methanol were the reviews of IPCS (1) and Kavet and Nauss (2). Knowledge about methanol toxicity in humans from high levels of exposure is available from acute intoxications (poisonings) in the general population, occupational exposures, and laboratory studies. The minimal lethal dose for methanol in untreated humans has been reported as a range of 300–1,000 mg/kg bw. Typical findings in acute methanol toxicity are temporary mild central nervous system depression followed by an asymptomatic period with a duration of 12–24 hours that is followed by metabolic acidosis. Ocular toxicity also develops in parallel with these effects. In severe poisonings, abdominal pain and difficulty breathing can occur and progress to coma and death due to respiratory failure. Five epidemiological studies reported symptoms such as headaches, dizziness, blurred vision, nausea, and/or eye irritation in workers exposed to methanol at concentrations exceeding the occupational limit of 200 ppm (1, 2). Observed symptoms from controlled exposures of limited duration, 200 ppm methanol for 75 minutes or 4 hours, were mild neurological effects characterized by fatigue, altered brain wave patterns in response to stimulus, and deficits in information processing, psychomotor skills, memory, and concentration (21, 22).

Studies in animals have examined methanol toxicity following acute or repeat dosing. The lethal dose in rats and rabbits was reported to be 2–3 times higher than the lethal dose reported for monkeys and 6–10 times higher than the lethal dose reported for humans (See Table 2-7). While humans experience acidosis and adverse visual effects following acute exposure to methanol, those effects do not occur in most laboratory animals such as rats, mice, rabbits, dogs, and minipigs. It is accepted that non-primate species may be appropriate models in studies that examine the direct alcoholic effects of methanol. A number of repeat dose studies identified the eye, brain, and liver as target organs in rats, dogs, and rabbits. The Expert Panel reviewed 3 repeat dose studies in which Sprague-Dawley rats were exposed with up to 5,000 ppm methanol vapors for 6 hours/day for 4 weeks (64-66). These studies demonstrated nasal irritation but no consistent signs of systemic toxicity. Histological examination inconsistently revealed thyroid and liver effects in rats exposed to 300 and 2,500 ppm methanol respectively; reproductive organ lesions were not observed. No signs of systemic toxicity or histological abnormalities were observed in Macaca fascicularis monkeys exposed with up to 5,000 ppm methanol vapors for 6 hours/day for 4 weeks, but it does not appear that reproductive organs were examined (64). No effects on weight gain or overt toxicity were noted in female M.fascicularis monkeys exposed to up to 1,800 ppm methanol vapors for about 11 months (41). An acute study by Youssef et al. (63) examined neurological effects in Long-Evans rats 10 minutes following gavage with 1,000, 2,000 or 3,000 mg/kg bw methanol and found no overt toxicity but noted a dose related reduction in operant running.

Genetic Toxicity

Results of *in vivo* genetic toxicity assays in mice have been mixed, with both negative and positive results in micronuclei formation and chromosomal aberration assays and negative results in SCE and urine mutagenicity assays (1, 67). Negative results were obtained in the majority of in vitro assays that examined mutations in bacteria and yeast, DNA repair in bacteria, and SCE and cell transformation in mammalian cells; positive results were obtained in a chromosomal malsegregation assay in yeast only in the absence of metabolic activation and in a mutation assay in mammalian cells only with metabolic activation (1). IPCS concluded that “The structure of methanol (by analogy with ethanol) does not suggest that it would be genotoxic.”

Carcinogenicity

There are no reliable data for evaluating carcinogenicity.
3.0 DEVELOPMENTAL TOXICITY DATA

This section contains reviews of original studies. Some tables are presented to assist the reader in the interpretation of the data. Smaller tables are included in the text for the reader’s convenience and are designated as Table 3-1, 3-2, etc. Larger tables are included in Section 7 and are designated as Table 7.3-A, 7.3-B, etc.

3.1 Human Data

Hantson et al. (68) reported a case of a 26 year old woman who ingested 250-500 mL of methanol in the 38th week of pregnancy. Five hours after methanol ingestion, the woman was slightly acidotic and had a serum methanol level of 2,300 mg/L and a formic acid concentration of 336 mg/L [note: There appears to be a discrepancy in the units used by authors for expressing methanol concentrations in mass versus molarity; based on the high level of intake, it appears that the unit of mass is correct]. Treatment consisted of ethanol and bicarbonate administration together with hemodialysis. Six days later, the woman gave birth to an infant with no signs of distress; Apgar scores were 9/10 and 10/10 at 1 and 5 minutes respectively. At the time of birth, the blood formic acid level was 2.4 mg/L in the mother and was below the detection level in the infant. A ten year follow-up of the child revealed no visual disturbances.

Lorente et al. (69) investigated the role of maternal occupational exposure in occurrence of cleft lip and palate. Data from the study was obtained from a multicenter European case-referent study utilizing 6 congenital malformation registers between 1989 and 1992. Occupational exposures during the first trimester were studied in 851 women; 100 cases had infants with oral clefts and 751 referents had healthy infants. The subjects were interviewed to determine occupational history and the types of products used on the job. An industrial hygienist reviewed interview responses to determine the probability of chemical exposures. Confounding factors considered included maternal age, socioeconomic status, residence, urbanization, country of origin, and medical history. Subjects were interviewed about smoking, and alcohol intake but it is not clear if the analyses considered those factors. Data were analyzed by estimating an adjusted odds ratio for each type of exposure and then conducting a stepwise logistic regression on all exposures with \( P \leq 20\% \). Analyses determined that at least 10% of the subjects were likely exposed to methanol during the first trimester of pregnancy. Odds ratios of 3.61 (95% C.I.: 0.91–14.4) and 3.77 (95% C.I.: 0.65–21.8) were calculated for methanol exposure and occurrence of cleft palate only and cleft lip with or without cleft palate, respectively. The authors reported no association between methanol exposure and oral clefts. Associations were reported for aliphatic aldehydes, glycol ethers, biocides, lead compounds, antineoplastic drugs, trichloroethylene, and aliphatic acids. Authors concluded that caution is required in the interpretation of these results due to the small numbers of subjects studied, but emphasized that some of these compounds are known or suspected reproductive toxins.

Strengths/Weaknesses: This study is unique in that it examines methanol exposure in humans and developmental outcomes.

Several weaknesses were noted in the study design. The study was not designed to look specifically at methanol. Presumably most subjects were exposed to complex mixtures. Exposure assessment were conducted according to occupation without individual measurements of chemical exposures. Methanol exposures were highly correlated with aliphatic alcohols in general. For methanol exposure as a subgroup, the numbers are too small to reach statistical
significance (only 2 with cleft palate and 4 with cleft lip with or without cleft palate exposed). Statistical procedures were not clearly defined. For example, table 5 in the study includes 11 significant exposures but these are apparently lumped together in the table into the 3 chemical families. Criteria for exclusion in the backward stepwise regression were not stated. There was no analysis of respondent/nonrespondent comparison.

**Utility (adequacy) for CERHR evaluation process:** If true, the odds ratios of 3.61 and 3.77 reported in this study between maternal methanol exposure and the risk of cleft lip and palate in offspring are substantial. Several factors limit the confidence that can be placed in a causal interpretation of these data, however. First, the confidence intervals around these point estimates are wide, and fail to exclude 1, indicating that the P-value associated with the odds ratio is not statistically significant. Thus the null hypothesis of no association cannot be formally rejected. Second, exposure was classified simply as “yes” or “no” on the basis of job title, with no information available on an individual’s exposure. Therefore, the study provides no information that is useful in establishing dose-response relationships. Third, many of the 96 chemical exposures were highly correlated with one another, although the authors attempted to reduce the resulting confounding by considering “only the broader exposure, representative of the chemical family...” and by selecting one exposure to be representative of a particular occupation (e.g., hairdressers). Backwards logistic regression analyses were conducted in which several candidate chemical exposures were included as predictors, but to the extent that the exposures were confounded, the resulting coefficients might be biased. In any case, for neither endpoint was the variable representing the general class of aliphatic alcohols retained in the final model, indicating that exposure to this class of chemicals was not associated with excess risk.

This study was not designed to look specifically at methanol and no individual exposure measurements were made. This limits any utility for CERHR. Due to the small numbers, the high correlation with other aliphatic alcohol exposure, and the resulting lack of statistical significance found, the Panel has low level of confidence in this study to provide elucidation of any link between methanol and the outcomes that were investigated.

Studies conducted in mice by Sakanashi et al. (70) and Fu et al. (67) have suggested that methanol exposure in folate-deficient mice increases the incidence of cleft palate (See Section 3.2.3). Those two publications cited epidemiological studies that examined the link between maternal folate levels during pregnancy and the incidence of cleft palate in humans. These epidemiological studies were reviewed in order to determine the relevancy of methanol exposure and folate deficiency in humans.

Peer et al. (71) conducted a study to determine the effects of Vitamin B₆ and Folic acid supplementation in women who had previously given birth to at least one child with cleft lip and/or palate. Of the 594 women in the study, 418 did not receive vitamins and 176 were given vitamins containing 5 mg folic acid and 10 mg Vitamin B₆ during the first trimester of pregnancy. The percentages of children with cleft/lip and/or palate were 4.7% in the group without vitamin supplementation and 2.2% in the group that received vitamins. The authors believed their study to be suggestive but not statistically significant.

**Strength/Weaknesses:** Several limitations in study design were noted. The value of this study is limited by its apparent ad hoc nature. The authors claim that a study “was begun to determine the effects of a prenatal vitamin capsule, supplemented with 5 mg of folic acid and 10 mg of B₆, administered during the first trimester to women who had previously given birth to one of more cleft lip and or cleft palate children”. Numerous methodological details are poorly reported. A total of 594 women were involved, although the source(s) of these patients, as well
as the inclusion and exclusion criteria applied, are not clearly presented. The reasons why only 176 took the vitamin supplement are also not explained (although women who became nauseated when taking them were advised to discontinue and were “dropped from the study”. How the compliance of the 176 women was ascertained is not described, nor are the procedures for confirming the presence or absence of cleft lip and/or palate in offspring. No statistical analyses of the data are reported. At the end of the report, the authors request that “additional colleagues will...send their data to the senior author”, apparently to be added to the database. It is not clear whether study procedures to be followed have been shared with these colleagues, however, throwing into question whether such data will be comparable.

Utility (Adequacy) for CERHR evaluation process: Overall, this study is of little use.

Tolarova and Harris (72) conducted a study to determine if periconceptual multivitamin and folic acid supplementation reduces the risk of giving birth to an infant with cleft lip and/or palate in high risk groups. The subjects for this study were obtained from a registry in the Czech Republic. Subjects consisted of women who previously gave birth to a child with cleft lip and/or palate (CL + P) between 1970–1982 and women with cleft lip or palate or women married to someone with cleft lip or palate born between 1930–1962. Subjects with syndromic or familial cases of cleft palate were excluded from the study. The supplementation group consisted of 221 women who agreed to take multivitamins containing 10 mg folic acid for at least 2 months prior to conceiving and during the first 3 months of pregnancy. The control group consisted of 1,901 women who either refused to participate in the study, began taking the multivitamin after the embryonic period, or stopped taking the vitamin before or during the embryonic period. Women participating in the study were given physical exams that included a gynecological evaluation and blood work. Unless affected by a seasonal affliction such as allergy, the women were urged to plan pregnancies for late spring or summer when more fresh produce is available. Statistical significance of findings were determined by chi-square tests and Fisher’s exact test. Of the 214 informative pregnancies in the supplemental group, 3 infants were born with oral cleft defects. One female infant had bilateral cleft lip and palate, one female had unilateral cleft lip and palate, and one male had a unilateral cleft lip. The authors noted a 65.4% decrease in clefts compared to expected values since the expected value was 8.7 cases with cleft based on family history (p=0.031). The incidence of cases of clefts in the supplemental group (1.4%) was lower than the incidence in the control group (4.0%). Authors noted that supplementation is most effective in preventing unilateral cleft (82.6% decrease, P=0.024) and in males versus females. The authors concluded that further studies are needed to determine whether the effective agent in periconceptual vitamin supplementation is folic acid, multivitamins, or both.

Strength/Weaknesses: The strengths of this study, conducted in the Czech Republic during the period 1976 to 1980, include the great care taken to assemble a homogeneous sample of women at increased risk of producing on offspring with cleft lip and/or palate. A detailed 10-step protocol was implemented in order to identify other medical causes of reproductive morbidity, as well as to eliminate syndromic and familial cases of CL ± P.

The weaknesses of the study are similar to those of other studies on this topic. First, women were not randomized to the folate supplementation and comparison groups, leaving open the possibility of residual confounding by some factors associated with a woman’s choice to supplement. Second, the supplementation consisted not only of folate but of a variety of vitamins as well, precluding the certain attribution of a beneficial effect of supplementation solely to folic acid. Third, the analyses, particularly those involving subgroups are limited by the small numbers of cases. For example, only 3 cases of CL ± P occurred among the 214 infants born to supplemented women, yet the authors draw fairly strong inferences, without any statistical basis,
of the beneficial effect of multivitamin supplementation on male probands with unilateral cleft. The occurrence of 1 additional child with clefting in one or another of the subgroups would have changed the results (e.g., the % reduction in occurrence) dramatically.

Utility (Adequacy) for CERHR evaluation process: The results of this study are consistent with those of several other experimental and observational studies in suggesting a reduction in oral clefting among women who took multivitamin supplements, but a causal interpretation is difficult to support.

Shaw et al. (73) conducted population-based case-control study to investigate if maternal multivitamin use reduced the risk of cleft palates in infants. California birth defect records from 1987 to 1989 were reviewed to identify infants or fetuses with cleft palate and/or cleft lip. Interviews were conducted in 731 cases and 734 controls to determine types and frequency of maternal supplement and cereal intake from 1 month before conception to 3 months afterwards. The information was used to estimate maternal folate intake levels. Confounding factors that were controlled included race, ethnicity, education, age, gravidity, smoking, and alcohol use. Use of folate-antagonistic medications and family history of oral facial clefts and epilepsy or diabetes were also considered. It was found that women who take folic acid-containing multivitamins periconceptually have a 25–50% decreased risk of having children with oro-facial clefts (odds ratios ranged from 0.50 with 95% CI of 0.36–0.68 to 0.73 with 95% CI of 0.46–1.2, depending on cleft phenotype). The risk of oral clefts was also reduced in women who did not take vitamins but ate folate-supplemented cereals. The authors cautioned that the association may not be due to folic acid but to other factors correlated with vitamin use such as another vitamin or mineral found in supplements or healthy behavior.

Strength/Weaknesses: The care with which this case-control study was conducted and reported provides a strong basis for confidence in its results. It is a population-based study, using the data of the California Birth Defects Monitoring Program. A large case series was assembled from births within a well-defined geographic/temporal setting, and controls were randomly selected. The case definitions applied were explicit and rigorously applied and verified. The statistical analyses were sophisticated, addressing the importance of a variety of potential confounders, including use of known folate antagonist medications, as well as of potential effect modifiers.

Among the weaknesses of this study is its retrospective design. Women were not randomly assigned to receive folate or non-folate preparations, reducing the confidence that can be placed in conclusions drawn about the causal role of folate in reducing the occurrence of oro-facial clefts, compared to other behaviors correlated with use of multivitamins containing folic acid. In addition, as the authors note, constituents of the multivitamin supplements other than folic acid might have been responsible for the beneficial effects. Folate use during pregnancy was ascertained by interviews conducted an average of 3.5 years after delivery. At that time, women were asked about consumption habits during the one-month period preceding conception and the three-month period following conception. At worst, this could introduce recall bias and at best, imprecision of recall regarding folate dose. The authors do provide persuasive evidence against the occurrence of recall bias, however. The folate dose had to be reconstructed based on the assumed folate contents of different vitamin preparations and cereals that the women reported using, creating the possibility of exposure misclassification and reduced precision of effect estimates. This might explain why no dose-response relationship was seen, with the odds ratios (OR) associated with different folate doses being more or less equivalent in magnitude. For most phenotypes and most doses, the 95% CI’s for the estimated odds ratios included 1, meaning that the odds ratios were not significantly different from 1. The OR’s for isolated cleft lip and/or
palate did not include 1 for “any use of multivitamins with folic acid” or with the two lower doses (0–.4 mg/day, 0.4–0.9).

**Utility (Adequacy) for CERHR evaluation process:** In summary, the results of this very well-conducted study are consistent with the hypothesis that use of folic-acid containing multivitamin supplements in early pregnancy are associated with reduced occurrence of orofacial clefting, and, furthermore, that concurrent alcohol use acts synergistically in producing this protective effect.

In 1984, Czeizel and Dudas (74) conducted a trial study in Hungary to determine if periconceptual vitamin supplementation could reduce the incidence of first occurrence neural-tube defects. Nulliparous women less than 35 years of age were randomly administered either a multi-vitamin supplement containing 0.8 mg folic acid or a trace element supplement containing only copper, manganese, zinc, and low levels of Vitamin C. The women were instructed to take the supplement daily for at least 1 month before attempting to become pregnant, while trying to conceive, and throughout the first 3 months of pregnancy. Confounding factors taken into consideration included demographics, intake of valproic acid or other teratogens, and family history of neural tube defects. Vitamin intake was confirmed by questioning the subjects and counting unused tablets returned by the subject. Statistical significance was determined by two-tailed chi-square and Fisher’s exact tests. There were no neural tube defects in the 2104 informative pregnancies in the vitamin supplementation group. Six cases of neural tube defects were observed among the 2052 informative pregnancies of the trace supplement group and the difference between the supplementation group was statistically significant. The authors noted that the rate of cleft lip with or without cleft palate in the vitamin supplementation group (1.9 per 1,000 births) was nearly twice the rate of the Hungarian population (1.0 per 1000 births). It was concluded by authors that these study results indicate that periconceptual vitamin supplementation reduced the incidence of first occurrence neural tube defects.

**Strength/Weaknesses:** The confidence that can be placed on the results of this study is enhanced by several of its characteristics. First, it is a randomized controlled trial rather than an observational study, thereby providing a stronger basis for drawing causal inferences. Second, systematic procedures were in place to ascertain compliance with the assigned treatment and to follow-up all pregnancies, including review of hospital and autopsy records, and investigation of all reports of a neural tube defect (NTD). Third, outcome definitions were clear and external oversight was provided to confirm case status. Fourth, the follow-up rate of very high, with pregnancy outcome ascertained in 99% of women who became pregnant.

Some limitations in study design were also noted. Although a significantly higher rate of NTDs was found in the trace-element group (6/2052 vs. 0/2104 in the vitamin-supplement group), the numbers of cases was clearly quite small, and the significance of the treatment group differences would be changed dramatically if 1 case were to have occurred in the vitamin group, or 1 fewer case had occurred in the trace-element group. The rate in the trace-element group was exactly what would be expected to occur in Hungary, so this small number of occurrences could have been predicted and incorporated into the study design to insure a large enough number of cases. It is presumed by the authors that it was the folate in the vitamin supplement that was responsible for the lower NTD rate, but the treatment differed in many respects. This presumption is not unreasonable based on other literature, but the complexity of the intervention represented by vitamin supplementation nevertheless leaves this possibility alive.

**Utility (Adequacy) for CERHR evaluation process:** Overall, this study suggests that 0.8 mg of folate daily reduces the risk of congenital malformations, and specifically, NTDs in offspring.
Thus, if exposure to methanol results in reduced folate levels in women, one result might be an increased risk of NTDs.

It is noted by CERHR that Czeizel and Dudas (74) were not the only investigators that failed to see a reduced risk of cleft palate following periconceptual supplementation. Discussions in studies by Shaw et al. (73) and Tolarova and Harris (72) identified at least 3 studies that did not find a link between multivitamin or folate supplementation and reduced risk of oral clefts (75-77). Three additional studies identified by Shaw et al. (73) or Tolarova and Harris (72) found correlations between multivitamin use and reductions in oral clefts (78-80). A literature search was not conducted to determine if more recent studies are now available.

McPartlin et al. (46) studied the breakdown and excretion of folic acid in pregnant woman. At one time point during each trimester of pregnancy and postpartum, 6 pregnant women were administered a nutritionally complete liquid enteral diet for 42 hours. During the last 24 hours of receiving the special diet, urine was collected and assayed for the breakdown products of folate, p-aminobenzoylglutamate (pABGlu) and p-acetamidobenzoylglutamate (apABGlu). Six non-pregnant woman of similar ages underwent the same procedure. The breakdown and excretion of folate during the first trimester was equivalent to the non-pregnant controls. During the second and third trimesters, breakdown and excretion of folate was significantly higher than in the non-pregnant controls and were highest during the second trimester. Postpartum breakdown and excretion of folate was not statistically different compared to the non-pregnant woman.

Strength/Weaknesses: Although the group numbers were small, the study was well conducted.

Utility (Adequacy) for CERHR evaluation process: This small but well-conducted metabolic study (N=6) demonstrates that folate metabolism changes over the course of pregnancy, accelerating in the second trimester and remaining elevated even into the postpartum period. The findings suggest that increased folic acid intake throughout pregnancy, but especially in the second (660 µg/day) and third trimesters (470 µg/day), is necessary. It appeared that folate catabolism was similar in the first trimester pregnant women and the non-pregnant woman, however, suggesting a need for 280 µg/day during the period of organogenesis.

In 1996 the Food and Drug Administration mandated the fortification of all enriched cereal grain products with folic acid (81). To assess the effects of folate fortification, the Centers for Disease control compared serum and red blood cell folate levels in woman of childbearing age (15–44 years) who participated in National Health and Nutrition Examination Surveys (NHANES) in 1988–1994 (n=5254–5261) versus 1999 (n=658–663). Mean serum folate levels rose from 6.3 ng/mL in 1988–1994 to 16.2 ng/mL in 1999. In red blood cells, which provide a better measure of long term folate status, the respective folate levels increased from 181 ng/mL to 315 ng/mL. The increases in folate levels occurred whether or not the women used vitamin/mineral supplements. Authors noted that the national health objective for 2010 is to increase the median red blood cell folate level to 220 ng/mL in non-pregnant women of childbearing age.

Conclusions for Folate Studies

These studies are consistent with the hypothesis that supplementation with vitamin preparations that include folate in varying amounts is associated with a reduction in the risk of first-time or recurrent oral clefting in offspring. One implication, then, is that any factor that reduces a pregnant woman’s folate level (e.g., methanol exposure) could possibly increase the risk of oral clefting. However, this argument involves several assumptions that would need to be worked out empirically, including: what is the dose-effect relationship between methanol exposure and folate
levels in pregnant women; does the relationship depend on the starting level of folate; in what proportion of the pregnant population would the reduction in folate level be sufficient to increase the risk of oral clefting in the offspring?

Studies in mice have provided evidence of increased neural tube defects and cleft palates in offspring of methanol exposed dams. While these human epidemiological studies are consistent with those findings they provide very limited evidence that can be used to support methanol exposure as the direct causative agent by way of decreasing available folic acid. Firstly, folate activity in the mouse is far greater than in primates and relevant enzyme activity in metabolism of formate may be different. Artificially folate deficient mice may be deficient in other relevant nutritional components. Relatively large embryotoxic doses were used to induce these defects in the rodents. Secondly, neither liver nor plasma or RBC folate activity was significantly impacted by methanol exposure in the mice (67, 70). In summary, the reduction in cleft palate and neural tube defects seen in humans with folic acid supplementation is consistent with and weakly supports the hypothetical mechanism of action of methanol reduction of folate activity in the rodent causing similar defects. Various interspecies differences make this extrapolation difficult.

3.2 Experimental Animal Data

3.2.1 Prenatal Development

As part of an effort to assess teratogenic effects of industrial alcohols, Nelson et al. (82) studied the effects of prenatal methanol exposure in Crl: Sprague-Dawley rats. Nelson et al exposed 15 pregnant rats per group to 0, 5,000, 10,000 or 20,000 ppm methanol (99.1% purity) for 7 hours/day (Table 7.3-A). The two lower dose groups were exposed on gd 1–19 whereas the 20,000 ppm group was exposed on gd 7–15. [It appears that some doses were evaluated in separate experiments. The rational for dose selection was not discussed]. Two groups of 15 control rats (one for the 10,000 and 20,000 ppm group and one for the 5,000 ppm groups) were exposed to air only. Blood methanol levels in concurrently-exposed, non-pregnant rats on days 1, 10, and 19 of exposure were measured by gas chromatography (GC) at 1.00–2.17, 1.84–2.24, and 5.25–8.65 mg/mL (31.2–67.7, 57.4–69.9, and 164–270 mM) in the low to high dose group, respectively. Background levels of blood methanol were not provided. The study authors assumed that blood methanol levels in pregnant rats were similar to those determined in non-pregnant rats. Maternal toxicity was evidenced by a slightly unsteady gait only in the high dose group during the first few days of exposure; there were no effects on body weights or food intake at any dose. The number of litters evaluated included 30 in the control group, 13 in low dose group, and 15 in the two highest doses. Statistical analysis of fetal data included analysis of variance (ANOVA) for weight effects, the Kruskal-Wallis test for parameters such as litter size and percent alive/litter, and Fisher’s exact test for malformations. For examination of skeletal effects, half the fetuses were fixed in 80% ethanol, macerated in 1.5% KOH, and stained with alizarin red S. The other half of fetuses were fixed in Bouin’s solution and examined for visceral effects. Statistically significant and dose-related reductions in fetal weight were observed in the 2 highest dose groups. The increased number of litters with skeletal or visceral malformations was statistically significant at the 20,000 ppm dose. A range of visceral malformations were observed including exencephaly and encephalocele. Rudimentary and extra cervical ribs were the skeletal effects observed at the greatest frequency at the 20,000 ppm dose. The authors concluded that methanol was a definite teratogen at 20,000 ppm, a developmental toxicant [decreased fetal weight] and possible teratogen [numerical elevation of some malformations] at 10,000 ppm, with a fetal no effect level of 5,000 ppm. A maternal NOAEL of 10,000 ppm was noted by the Expert Panel.
**Strengths/Weaknesses:** This is a prenatal developmental toxicity study of standard design with the number of animals per dose group (n=15) adequate for the time the study was performed. Endpoints observed were appropriate for a prenatal toxicity study. There was an effort to determine blood methanol concentrations. The purity of methanol was reported, chamber methanol concentrations were monitored, and adequate statistical analyses were conducted.

A limitation was the measurement of blood methanol concentrations in non-pregnant instead of pregnant females. Although a different (shorter) duration of exposure was used for the 20,000 ppm group, the limiting effect is minor given that this dose was clearly a developmental toxicant and teratogen.

**Utility (adequacy) for CERHR evaluation process:** Maternal and developmental NOAELs were identified for this study. The Panel’s confidence in the data is high and has clear utility in defining the broad dose range at which prenatal developmental toxicity is observed in the rat.

Rogers et al. (83) examined the sensitivity of Crl:CD-1 mice to the developmental toxicity of inhaled methanol (Table 7.3-B). In the original 3 block design, groups of mice were exposed to 1 of four doses of methanol vapors (Fisher Scientific (2001) Optima grade, ≥99.9% purity) for 7 hours per day on gd 6–15. The doses and numbers of mice per dose (in parentheses) were air-exposed control (114), 1,000 (40), 2,000 (80), 5,000 (79), and 15,000 (44) ppm. A final block of mice was added to fill in intermediate concentrations of 7,500 (30), and 10,000 (30) ppm. [The rational for dose selection was not discussed.] During the seven hour inhalation exposure period, treated and air exposed mice were deprived of food but had access to water. An additional set of 88 controls were not handled (remained in their home cage) and fed ad libitum. Another group of 30 control mice remained in their home cage and were food deprived for 7 hours per day on gd 6–15. Approximately 3 pregnant mice per block/treatment group were killed following exposure on gd 6, 10 or 15 and their blood was collected for plasma methanol analyses by GC. The mean plasma methanol concentrations averaged for the three gestational days were 0.0016, 0.097, 0.537, 1.650, 3.178, 4.204, and 7.330 mg/mL [0.05, 3.0, 16.8, 51.5, 99.2, 131, and 229 mM] in the control to high-dose groups, respectively. Methanol concentrations were dose-related, did not appear to reach saturation, and were not consistently affected by gestation day or previous days of exposure. Analysis of plasma methanol levels was conducted in a few non-pregnant mice and there appeared to be no differences compared to pregnant mice. Rogers et al. (83) noted that plasma levels at a given methanol concentration were lower in non-pregnant rats exposed through a similar protocol by Nelson et al. (82).

Following sacrifice of dams on gd 17, Roger’s et al. (83) compared developmental effects in treated groups to effects in the chamber air-exposed control group. Dams and litters were considered the statistical unit and the numbers evaluated are listed under Table 7.3-B. Statistical analysis included the General Linear Models procedure and multiple T-test of least squares method for continuous variables and the Fisher’s exact test for dichotomous variables. The chamber air-exposed control dams gained significantly less weight than both types of cage controls. Methanol exposure did not produce overt intoxication or further reduce weight gain in dams. There was a dose related and statistically significant decrease in the number of live pups per litter in groups exposed to methanol vapor doses of 7,500 ppm and higher; there was also a dose-related increase in females with fully resorbed litters at 10,000 ppm and higher. The incidence of cleft palate was increased at doses of 5,000 ppm and greater. The percent incidence/litter of exencephaly was significantly increased at the 10,000 and 15,000 ppm doses. Only fetuses from the 1,000, 2,000, 5,000, and 15,000 ppm groups were examined for either skeletal malformations or visceral defects. Skeletal effects were examined in half the fetuses that
were fixed in 70% ethanol, macerated with 1% KOH, and stained with Alizarin red S. Visceral effects were examined in the other half of fetuses that were fixed in Bodian’s solution. Delayed ossification effects were commonly observed at the 15,000 ppm dose whereas several skeletal anomalies were seen at doses of 5,000 ppm and higher. The effect observed at the lowest exposure level was increased incidence of cervical ribs that occurred at 2,000 ppm. The effect at this dose was statistically significant in a pairwise comparison and showed a dose-response relationship.

In this same study by Rogers et al. (83), additional pregnant mice were exposed to methanol by the oral route to determine comparability across exposure route (Table 7.3-C). On gd 6-15, 20 mice were gavaged with methanol twice daily at a dose of 2,000 mg/kg for a total dose of 4,000 mg/kg/day and 8 control pregnant mice were gavaged twice daily with water. The dose was selected to produce blood methanol levels observed in the inhalation study at the higher doses. Twice daily gavage doses of 2,000 mg/kg methanol (8 mice) on gd 6–15 gave a pattern of response similar to that seen in the mouse group exposed to 10,000 ppm by inhalation. Mean maternal blood methanol levels one hour following the second daily exposure (3.856 mg/ml = 120 mM) were slightly lower than blood levels in dams inhaling 10,000 ppm methanol in a previous experiment (4.204 mg/ml = 131 mM). Fetal effects in the treated group included decreased fetal weight, increased resorptions, decreased live fetuses, and an increased incidence of fetuses/litter with cleft palate or exencephaly. Statistical significance of effects is indicated in Table 7.3-C.

Rogers et al identified a developmental LOAEL of 2,000 ppm and a NOAEL of 1,000 ppm. Benchmark doses were also calculated. The benchmark doses for a 5% added risk (BMD\textsubscript{05}) from the lower 95% confidence limit on the maximum likelihood estimates (MLE) are generally consistent with NOAELs (Table 3-1).

\textsuperscript{a} mean plasma methanol concentration

**Strengths/Weaknesses:** Strengths of this study of prenatal development included wide range of dose levels used, quantification of internal dose through the measurement of plasma methanol levels, achievement of very stable vapor concentrations, use of a sufficient number of pregnant animals for most comparisons, evaluation of appropriate endpoints for a prenatal study, appropriate statistical analyses, and calculation of benchmark doses. The study was well-controlled with the use of cage control mice that were not handled or not handled and food deprived.

Limitations included limited fetal examinations performed at concentrations of 7,500 and 10,000 ppm, measurement of plasma methanol levels in only three animals at three time points, and no reporting of number of fetuses and litters with skeletal defects (only litter means reported).
Utility (adequacy) for CERHR evaluation process: The Panel’s confidence in these data is high. The data provide adequate expression of prenatal dose-effects over a range of exposure concentrations. The results of the oral gavage study provide a minimal basis for assessing comparability of effect from inhalation and oral gavage exposure and it provides data that supports the belief that blood level equivalence is the significant factor rather than route of exposure.

Cummings (84) conducted studies in rats to examine reproductive physiology and embryo/fetotoxicity following early pregnancy exposure to methanol (high purity solvent grade). Holtzman rats (from the Small Animal Supply Co.) were gavaged with water or 1,600, 2,400, or 3,200 mg/kg bw/day methanol in water on gd 1–8 (Table 7.3-D). Based on conversion factors reported by Mole et al. (1990), the author estimated that peak blood methanol levels would be 1.875, 2.8, and 3.7 mg/ml (~58, 87, and 115 mM) in the low to high dose dams respectively. Those blood levels are estimated to equal blood levels resulting from exposure to 10,000, 15,500, or 21,000 ppm methanol vapor, respectively, for six hours. Eight rats/group were sacrificed on gd 9, 11, and 20. Data was analyzed using general linear models and when a significant ANOVA was detected, data were further analyzed by multiple t-tests of least square means. On gd 9, gravid uterine weight was significantly reduced in dams at all doses and a significant decrease in implantation site weight was first noted in the mid dose group. Also noted was a significantly decreased maternal body weight and an increased number of small implantation sites with extravasated blood in the high dose group. Methanol treatment had no effect on the number of implantation sites or corpora lutea, ovarian weight, or serum levels of progesterone, estradiol, luteinizing hormone, and prolactin on the day following the last dose of methanol. An examination of embryonic development on gd 11 revealed no effects on the yolk sac diameter, fetal size, number of somites, viability, or overall development. When litters were examined on gd 20 there were no effects noted on litter size, fetal weight, or resorptions. Fetuses were only assessed for external abnormalities and none were observed. Maternal ovary weight and corpora lutea counts were determined in dams sacrificed on gd 9 and 20 and there were no effects noted. In contrast to results obtained on gd 9, methanol did not affect uterine weight on GD 20. Additionally, the decreased maternal body weight observed at gd 9 after the highest dose of methanol was not observed on gd 20. The authors also studied decidual cell response (DCR) in pseudopregnant rats. Results indicated that effects on uterine weight and implantation sites on gd 9 may have resulted from methanol induced inhibition of the DCR. The author concluded that chemical exposure may cause some impairment of the DCR without necessarily affecting implantation success. [The Expert Panel observed that there was no increase in resorptions on gd 20 at the highest methanol dose used, leading one to question whether the atypical sites observed on gd 9 represented a significant toxic manifestation. Further, the general lack of response is difficult to interpret given that there are no data in this strain that characterizes the general pattern of developmental toxicity following traditional (gd 6–15) periods of dosing.]

Strengths/Weaknesses: The strengths of study design are the use of three doses, reporting of methanol grade, and the examination of endpoints during different dosing periods.

Study limitations included the small number of pregnant rats used in each group and performance of only external gross examinations with no examination of possible visceral or skeletal defects. It was not stated if animals were randomly assigned to treatment groups. It is not clear if the litter or the fetus was used as the experimental unit for statistical analyses. Hormone levels were measured at only a single time point and it is not clear how much time had elapsed between the final methanol dose and the time of sacrifice.
Utility (adequacy) for CERHR evaluation process: The Panel’s confidence in these data is low due to the weaknesses in the study. Some of these data may have confirmatory value if other studies without these limitations show relevant effects.

Youssef et al. (85) conducted a study to determine toxicity of methanol in rats following oral administration at a single time point (Table 7.3-E). On gd 10, 10–12 Crl: Long-Evans rats were gavaged with methanol [Aldrich (2001) HPLC grade (99.93% purity)] at 1.3, 2.6, or 5.2 mL/kg bw (1,023, 2,045, or 4,090 mg/kg bw according to CERHR calculations). The doses were selected according to guidelines for segment II studies that require one maternally toxic dose equal to 40% of the LD$_{50}$. The rats were first gavaged with mineral oil to prevent gastric irritation. A control group of 9 rats was not gavaged and a control group of 4 rats was gavaged with mineral oil. Because no differences were found between the two control groups data were combined into a single control group. Dams were sacrificed and necropsied on gd 20 and 10–13 dams and fetuses were examined/group. Statistical analysis for fetal anomalies and variations included ANOVA, the Fischer PLSD exact test, and determination of dose-response relationships. Both the individual fetus and litter were considered statistical units. Signs of maternal toxicity were limited to the high dose group and included significantly decreased bodyweight gain and food intake. There were no signs of intoxication and a histological evaluation of tissues in 2 dams/group revealed no effects on liver, spleen, heart, lungs, and kidneys. Fetuses were examined grossly and the heads and skeleton were examined for malformations according to the Dawson method. Methanol exposure did not increase prenatal fetal mortality. Bodyweights of fetuses were significantly reduced in all treatment groups, but the response was not dose-related. The numbers of fetuses with anomalies or variations was significantly increased at all doses. Dose-related anomalies included undescended testes and eye defects (exophthalmia and anophthalmia) that reached statistical significance in fetuses and litters of the high dose group. Other fetal effects that appeared to be dose related included facial hemorrhage, and dilated renal pelvis. Authors noted that in contrast to previous rodent studies, exencephaly was not observed. According to authors, possible reasons for this discrepancy include differences in day of dosing, dose level, route of administration, or interspecies effect.

Strengths and Weaknesses: The strengths of this study are the complete examination of the fetuses (gross, visceral and skeletal) and a thorough analysis of the data. Animals were randomly assigned to treatment groups, a sufficient number of animals were used, and methanol purity was reported.

The weaknesses in this study design is that treatment occurred on a single day of gestation that is not the day most sensitive to developmental toxicity effects of methanol. Further the effect of mineral oil gavage prior to methanol gavage on absorption kinetics is not known.

Utility (adequacy) for CERHR evaluation process: The utility of these data are limited due to timing of the single dose and lack of understanding of dosing regimen on blood methanol concentrations.

A review of developmental effects observed by NEDO was conducted by IPCS (7), HEI (86), and ILSI (87). Following exposure of Sprague-Dawley rats to 200, 1,000, or 5,000 ppm methanol vapors on gd 7–17 for 22 hours/day, maternal toxicity and fetal mortality and malformations were observed in the 5,000 ppm group. IPCS also reported a reduction in fetal brain, thyroid, and thymus weight with no histopathological changes at the 5,000 ppm dose. Another NEDO study reported a lack of teratogenic effects in monkeys that inhaled 1,000 ppm methanol vapors for 22 hours/day for up to 30 months. ILSI concluded that the NEDO studies were not adequately reported and that findings need to be verified in other laboratories.
3.2.2 Postnatal Development

Infurna and Weiss (88) conducted a study to assess maternal and neonatal behavioral effects in Long-Evans rats (90–120 days old from Blue Spruce Farms) and their offspring when dams were exposed to 2% methanol [purity not specified] in water on either gd 15–17 or gd 17–19 (Table 7.3-F). There were 10 dams in the control and each treatment group. The authors reported that water consumption was similar in treated and control groups; the lack of preference for the water versus the 2% methanol solution was the basis for dose selection. The daily consumption of methanol averaged 2,500 mg/kg bw/day. Data were analyzed by one-way ANOVA with the litter serving as the unit of observation. There was no effect on gestational length or maternal body weight. Maternal behavior was unaffected as judged by the time for the dam to retrieve pups after they were weighed and returned to the cage. Methanol treatment had no effect on litter size, pup birth weight, postnatal weight gain, postnatal mortality, or day of eye opening. Neurobehavior tests revealed effects in offspring of methanol treated dams in both dose groups. On pnd 1, 3–5 pups/litter were tested for suckling ability and the proportion of pups successfully attaching to nipples was not significantly different across the three groups. However, the mean latency to nipple attachment was significantly longer in the methanol treated groups; there was no statistically significant difference between the methanol treatment groups. On pnd 10, 8 pups/group were tested for homing behavior; specifically, the ability to locate home nesting material within a cage containing 4 squares of clean shavings and one square with material from the pups home cage. There were statistically significant differences between the performance of treated pups when compared to controls. It took about twice as long for the treated pups to reach the home area and they took less direct paths than the control pups. There was no difference in performance between the two methanol treated groups. Citing unpublished data, placental transfer of $^{14}$C-methanol was reported to occur in rats exposed overnight to 2% methanol in water with fetal brain levels reaching 30um/g. The authors stated that the results of their study indicate that methanol can be defined as a behavioral teratogen in rats.

Strengths/Weaknesses: The strengths of this study were a stress-free exposure route (pilot study showed rats chose equally the methanol or water solutions), sensitive measures of neonatal behavior, finding of an effect, random assignment of animals to groups, a sufficient number of animals, and appropriate statistical analyses.

A weakness of this study is that single dose design precluded determination of the existence of a dose-effect. In addition, the purity of methanol was not reported.

Utility (adequacy) for CERHR evaluation process: The utility of the study may be limited by uncertainty implicit in any toxicological response where there is no dose response data and the inability to place these behavioral effects in the context of other potential positive controls.

Stanton et al. (89) assessed the postnatal effects of in utero methanol exposure by examining a range of functional, physiological, and behavioral parameters. Those parameters included neonatal mortality and body weight, motor activity, olfactory learning/retention, behavioral thermoregulation, T-maze delayed alternation learning, acoustic startle response, pubertal development, motor activity, reflex modification audiometry, passive avoidance, and visual evoked potentials. Groups of 6–7 Crl: Long-Evans rats were exposed to air or 15,000 ppm methanol vapors (Fisher Scientific (2001) Optima grade, ≥99.9% purity) for 7 hours/day on gd 7–19 (Table 7.3-G). That dose was chosen because it was the highest vapor level that could be obtained without producing an aerosol and because it was halfway between doses that were non-teratogenic (10,000 ppm) and teratogenic (20,000 ppm) in the Nelson et al. (82) study. The
authors estimated that treated dams received a dose of 6,100 mg/kg bw/day. Maternal serum methanol levels were measured after exposure on gd 7, 10, 14, and 18. Methanol concentrations were highest on gd 7 at 3.826 mg/ml (119 mM) and gradually decreased to a level of 3.169 mg/ml (98.9 mM) by gd 12. The only effect noted in dams was lower bodyweight on the first two days of exposure. All but 1 dam each in the control and treated groups delivered litters. Sacrifice and necropsy of dams on pnd 23 revealed no increase in postimplantation loss. External examination of pups revealed one missing eye in two pups from the same litter in the methanol exposed group. Postnatal bodyweights were modestly but statistically significantly lower in treated pups on pnd 1, 21, and 35, but there was no increase in postnatal mortality. Methanol treatment did not affect the age of preputial separation, but vaginal opening was delayed by 1.7 days. Because larger variations in pubertal development have been observed with known reproductive toxins, the authors noted that this small delay in vaginal opening is probably not an adverse reproductive effect. Neurological testing was performed with tests conducted on specific days up to pnd 160, with some animals being exposed to multiple tests. In most tests, 1/pup/sex/litter was examined. Behavioral data were analyzed by one-way ANOVA with the litter as the unit of observation. The neurobehavioral battery failed to indicate any effect of methanol exposure on multiple measures of sensory, motor and cognitive functioning when these animals were tested on postnatal days thirteen to sixty-three. The two animals with anophthalmia had aberrant visually evoked potentials.

Strengths/Weaknesses: The strengths are that a number of different functions were assessed using a variety of measures. This would have been very important if effects had been found, to confirm their generality. The exposure dose and duration were reasonable choices, given the status of prior studies, and were well documented. Elevated maternal blood levels of methanol confirmed that actual exposure occurred and were in general agreement with an earlier study in rats (Nelson et al. 1985). In addition, dams were matched for body weight and then randomly assigned to treatment groups, the purity of methanol was reported, and methanol concentrations in chambers were measured and reported.

The overarching weakness of the study is that effects were not found and that the group size, (n=6–7 with litter as the unit of measure) was too small for the tests employed to have statistical power to pick up deficits with known developmental neurotoxicants. The concentration of 15,000 ppm and/or duration (11 days) of exposure is in the range that produced evidence of prenatal developmental toxicity in rats.

Utility (adequacy) for CERHR evaluation process: This study revealed no effects on survival but decreased body weights in offspring from dams exposed prenatally to methanol vapors. The body weight effects were seen at birth and persisted through postnatal day 35. The utility of the absence of neurobehavioral effect is limited due to the small group sample size.

Weiss et al. (90-92) sought to determine neurological effects in rat pups whose dams were exposed to methanol vapor for 6 hours/day from gd 6 through pnd 21 (Table 7.3-H). The Expert Panel notes that since litter and dam were exposed in the postnatal period, pup exposure during this time was direct and possibly through milk. Four cohorts of Crl: Long-Evans hooded rats (n=10–12 dams/treatment group/cohort) inhaled 0 (air only) or 4,500 ppm methanol vapor (HPLC grade) for six hours daily. The dose selection was based upon doses in other neurobehavioral studies. Three neonatal tests were selected to assess neurobehavior: 1) the suckling test which measured the latency time to nipple attachment; 2) Conditioned olfactory aversion test that evaluated the sensory capabilities of neonates; and 3) a motor activity test. Two tests were performed on pups when they became adults; one assessed motor function and operant behavior while the second assessed cognitive function. A total of 13–26 rats/group were evaluated in
neonatal tests and 8–13 rats/group were examined in adult tests of neurotoxicity. Data were analyzed by repeated measures ANOVA including both between and within animal factors.

Dam blood methanol concentrations were similar during gestation and lactation with a mean level of ~550 mg/L (17.2 mM). Mean blood methanol levels, measured in pups on pnd 7 and 14, averaged 1260 mg/L, a bit more than twice the level of dams. Methanol levels in pups began a steady decline starting at pnd 11 and reached levels that were equivalent to maternal concentrations on pnd 48. There were no effects on dam weight gain during pregnancy, litter size, or postnatal pup weight gain to pnd 18. No effect on latency time to nipple attachment was observed when pups were tested on pnd 5. Methanol exposure had no effect on conditioned olfactory aversion response when pups were tested on pnd 10. Motor activity of treated pups was variable, being decreased on pnd 18 but increased on pnd 25. Neurological testing of pups was conducted prior to methanol exposure on pnd 18, but residual levels of methanol prior to testing were not measured. On pnd 25, four days had elapsed since the last methanol exposure. The authors opined that pnd 18 results were not likely due to residual methanol. In the test performed when pups were adults, small differences between control and treated adult offspring were noted in the fixed wheel running test only when results were analyzed separately by sex. The test measured motor function and operant behavior by assessing the ability of the rats to run in a wheel that had to be rotated a fixed number of times to receive a food pellet. Males were required to turn the wheel a greater number of times (FR 28) than females (FR 20) and this may have accounted for the differences in response per sex. Results of the stochastic spatial discrimination test indicated that methanol exposure may produce subtle cognitive defects. The test measured how quickly the rats learned to press a series of levers in a sequence that rewarded them with a food pellet. In the first test conducted, there were no differences between control and treated rats. In a second test with a new sequence of lever responses, it was found that control rats learned the new sequence slightly faster than treated rats.

Morphological examination of brains revealed that methanol treatment did not delay neuronal migration, increase numbers of apoptotic cells in the cortex or germinal zones, or produce defective myelination on pnd 1 or 21. However NCAM 140 and NCAM 180 expression were reduced in treated rats on pnd 4 but such differences were not apparent in rats killed 15 months after their last exposure. NCAMs are a family of glycoproteins that are needed for migration, axonal outgrowth, and establishment of the pattern for mature neuronal function.

A Health Effects Institute (HEI) Review Committee evaluated the study by Weiss et al. (90) and concluded that “…the investigators conducted many tests and found only isolated positive results that were small and variable. Because no compensation was made for multiple testing, care must be taken not to ascribe too much significance to these results.”

The Expert Panel noted the two-fold greater blood methanol concentration in neonatal pups compared to their dams when both were exposed to the methanol vapor. Several plausible factors may account for this difference: 1) pups skin likely has a faster rate of skin absorption; 2) pups have a proportionally larger surface area per unit weight than do adults; 3) metabolism/excretion rates may be slower in neonates; 4) pups also are exposed to methanol through maternal milk.

Strengths/Weaknesses: A strength of this study is that it extended the dosing period into the postnatal period to more fully cover the extended period of brain development in the rat. The spectrum of neurobehavioral tests were also broader than those originally utilized by Infurna and Weiss (88). In addition, a sufficient number of animals were randomly assigned to treatment groups, statistical analyses were appropriate, methanol purity was reported, and concentrations of methanol in chambers was measured and reported.
A weakness of this study was the lack of immunohistochemical studies to verify the NCAM expression findings.

Utility (adequacy) for CERHR evaluation process: The study indicated that there was no effect on viability and bodyweight of pups exposed prenatally and through postnatal day 21. This study identified that blood methanol concentrations were approximately two-fold greater in nursing pups when compared to maternal levels. While some of this difference plausibly reflects innate age-related differences in toxicokinetics, exposure to methanol through mother’s milk in addition to direct vapor exposure likely accounts for the majority of the difference. This study suggests that methanol exposure produced gender-related differences in methanol exposed pups in a test that assessed cognitive and motor function when the pups were tested as adults. Transient changes in NCAM isoforms were observed that could be suggestive of alterations in developmental processes (altered migration and differentiation). However, no gross neuropathological changes were found and immuno-histochemical studies, that could have corroborated these findings, were not performed. An experimental design that does not permit evaluation of dose-response adds uncertainty to the utility of the findings.

Burbacher et al. (41, 93) evaluated the reproductive and developmental effects associated with methanol exposure in Macaca fascicularis monkeys. In the study, two cohorts of monkeys (6/dose/group/cohort) were exposed to air only in chambers or 200, 600, or 1,800 ppm methanol vapors (99.9% purity) for 2.5 hours/day during a premating and mating period (about 180 days), and during the entire pregnancy (about 168 days) (Table 7.3-I). Doses were selected to produce blood methanol concentrations from just above background to just below levels resulting in non-linear clearance kinetics. Monkeys in cohort 1 were all feral born and were 5.5–11 years old. Cohort 2 was made up of 15 feral born monkeys and 9 colony-bred monkeys (Texas Primate Center, Charles River Primates, CV Primates, or Johns Hopkins University) aged 5–13 years. The 2 cohort design was selected to reduce the number of animals tested at the same time, but maintain an adequate sample size. Postnatal growth was monitored in the infants and neurological assessments were conducted to evaluate newborn health, reflexes, behavioral responses, and visual, sensorimotor, cognitive, and social behavioral development. A toxicokinetic study was also conducted and is described in detail in Section 2.1.3. Statistical analysis in this study included one-way ANOVA (to analyze growth, sensorimotor development, neonatal responses, and spatial and recognition memory), repeated measures ANOVA (to analyze social behavior and secondary-outcome variables from the Spatial Memory test), and goodness-of-fit of all linear models through assessment of residuals.

Biweekly analysis of maternal methanol and formate blood concentrations revealed dose-related increases in methanol but not formate levels throughout the exposure period, including pregnancy as described in Section 2.1.3. No information on fetal methanol or formate levels was collected. Maternal weight gain was not consistently affected and there were no clinical signs of toxicity. Methanol exposure had no effect on menstrual cycles prior to or during mating, conception rate, or live birth index. The duration of pregnancy was reduced in all methanol treated groups but was not dose-related and was within the reported normal range for this species. One infant in the high dose group was born after a 150 day gestation period and showed signs of prematurity including irregular breathing and body temperature, difficulty feeding, and a lower birth weight. Caesarian (C)-sections were conducted in two monkeys in the 200 ppm group and 2 in the 600 ppm group who experienced vaginal bleeding presumably due to placental detachment. Two C-sections were performed in the 1,800 ppm group. The first C-section was conducted to deliver a dead fetus that was found to have hydrocephaly and autolysis of all the major organs.
The second C-section was performed because the monkey experienced 3 nights of unproductive labor. One infant in the control group and one in the 600 ppm group were stillborn due to asphyxiation during delivery.

Neurobehavioral testing was conducted during the first 9 months of life in a total of 8–9 infants/group, and revealed 2 effects that may have been due to methanol exposure. The Visually Directed Reaching Test evaluated the infants sensorimotor development by determining their ability to reach for a brightly colored object containing a nipple dipped in applesauce. Performance of male infants in the Visually Directed Reaching Test was reduced in all treated groups. The mean ages for achieving the criteria of the test were 24, 32, 43, and 41 days for males in the control to high dose groups, respectively. The results of the Visually Directed Reaching test were not significant when males and females were evaluated together (ANOVA p = 0.20); when evaluated by sex, significance was obtained for males in the 600 ppm and 1,800 ppm groups (ANOVA p<0.04). The Fagan Test of Infant Intelligence assesses the time an infant spends looking at a familiar versus novel object and was conducted in the monkeys when they were 190–210-days-old. The Fagan test has been shown to reflect information processing, attention, and visual memory function in human and non-human primate infants and correlates well with IQ measures in children at later ages. In tests using monkey faces, it was found that only the control infants spent more than 60% of the time looking at novel versus familiar faces. All three groups of prenatally methanol-exposed infants failed to show a significant preference for novel social stimuli (pictures of monkey faces), whereas the control group did show a significant novelty preference as expected. However, performance was not concentration-related, nor was there a significant overall methanol effect across the four groups (ANOVA p = 0.38). Methanol exposure had no effect on the remaining neurobehavioral tests that examined early reflex responses, gross motor development, spatial and concept learning and memory, and social behavior. Visual acuity, an important marker of methanol-induced toxicity, could not be evaluated due to a high test failure rate in control and treatment groups. Methanol exposure had no effects on infant growth or age of tooth eruption. However, at 12 and 17 months of age, two females in the 1,800 ppm group experienced a wasting syndrome that occurred despite normal food intake. Tests for viral infection, hematology, blood chemistry, and liver, kidney, thyroid, and pancreas function revealed no cause for the symptoms. Both monkeys were euthanized and necropsies demonstrated severe malnutrition and gastroenteritis.

A committee assembled by HEI to review the Burbacher et al. (41, 93) study expressed confidence in the data because the study was well designed and executed. The wasting syndrome observed in two females of the high dose group was identified as the most concerning result by these reviewers. The committee noted the lack of dose response for the reduced gestation period in treated monkeys and also noted that there were no differences in body weight or other physical parameters of infants. They suggested that adrenocorticotropic hormone levels be measured in neonates in future studies to determine if premature labor was triggered by precocious development of fetal hypothalamus, anterior pituitary, or adrenal cortex. The committee urged caution in the interpretation of the two positive neurobehavioral effects since small numbers of animals were analyzed per group, especially for sex and cohort specific analysis where most significant effects were noted. In addition, the Committee noted that the results were not adjusted for multiple testing, there were usually no dose-response relationships, and results were inconsistent among the methanol exposure groups. Effects were small and often varied more between cohorts than treatment groups.

The Panel noted that Dr. Alice Tarantal, a primate reproduction expert from the California Regional Primate Research Center, also reviewed the reproductive findings of the Burbacher et
al. (93) study for the American Forrest and Paper Association (94). Dr. Tarantall noted that there may be an association between methanol exposure and early deliveries. However she concluded that findings are more likely coincidental and of limited biological significance since 1) all deliveries were within the range of historically observed gestational ages for *Macaca fascicularis* and 2) the birth weight and size of all infants were within normal ranges. Dr. Tarantall stated that there does not appear to be sufficient evidence to support the claim of increased pregnancy complications following methanol exposure. She stated that vaginal bleeding sometimes occurs in macaques 1-4 days prior to delivery of a healthy infant and that it does necessarily imply a risk to the fetus. An ultrasound examination would have been required to diagnose fetal or placental problems. Lastly, Dr. Tarantall stated that “It would be useful to review the findings discussed above within the context of normative colony data.”

**Strengths/Weaknesses:** The general strength of this study is that it is detailed and well-designed with long dosing and follow-up periods and a thorough behavioral assessment. In addition, the animals were first separated into groups based on age, size, and parity and then randomly assigned to exposure groups. Purity of methanol was reported and concentrations in chambers were monitored and reported. The strengths of these data in terms of a reproductive evaluation are the use of a relevant subhuman primate model in sufficient numbers to make initial evaluations meaningful, a carefully-designed and executed exposure situation, and evaluation of functional endpoints that comprise female reproduction and are sensitive to toxicant perturbations.

The number of animals used (n = 9-10) was large for a non-human primate study. However, the numbers of animals and singleton births, makes this study, like many other primate studies, vulnerable to individual accidents that may or may not be treatment-related, thus reducing the power of the study. One weakness of the study is that small numbers of animals (n = 2-4/group) were used during the analyses of subgroups such as sex and cohort. In addition, no correction for multiple comparisons was made. However, it is not clear, what would be the most appropriate adjustment to make in this instance, because the concept of having a battery of tests is to evaluate different domains of function that are presumably somewhat, if not entirely, independent of each other.

Although most tests were negative, two critical findings were apparent on tests in the neurobehavioral battery used in this primate study. First a delay in sensorimotor development (assessed by the Visually directed reaching test) was noted in male offspring during the first month of life. Delays in sensorimotor development were concentration-related as evidenced by delays of approximately 9 days for the 200 ppm (260 mg/m$^3$) group to more than 2 weeks for the 600 and 1800 ppm (780 and 2300 mg/m$^3$) groups. Second, the offspring prenatally exposed to methanol did not perform as well as controls on the Fagan Test of Infant Intelligence. Although there were not concentration-related trends observed in the Fagan test, this could well reflect the inherent constraints of the measured endpoint, which typically is an approximately 60% response preference for novel stimuli *vis-a-vis* a 50% chance response level. If the control group performs at the 60% level and the most impaired subjects perform at approximately the 50% chance level (worse than chance performance would not be expected), the range over which a concentration-response relationship can be expressed is necessarily quite limited, and thus the lack of a clear monotonic trend is not surprising.

The number of animals in each group was small and no robust concentration-response relationship was observed for most of the effects observed. Actually, for the sensorimotor effects, a concentration-related trend was evident in the data for males and for both sexes combined (although not for the females alone); the basis for the gender-specific nature of this
finding is unknown, but other developmental neurobehavioral phenomena, including the
developmental toxicity of ethanol (95, 96), are known to differ between sexes, and thus cannot be
dismissed as necessarily chance occurrences.

Utility (adequacy) for CERHR evaluation process: Expert Panel members came to different
conclusions about the utility of the reproductive and/or developmental findings. One panel
member made the following conclusion:

No significant effects distinguished the methanol-exposed groups from the control group, except
for a statistically significant (p = 0.03) decrease in the duration of pregnancy. Pregnancies
resulting in live births were about 6–8 days (5%) shorter in the methanol-exposed groups.
Although no other adverse reproductive outcomes (e.g., reduced fertility, spontaneous abortion,
reduced neonatal size or weight) were statistically significant, it is noteworthy that caesarian
sections were performed only on methanol-exposed females, that is, two C-sections per group for
a total of six in the methanol groups versus no C-sections in the controls. These operations were
performed in response to signs of difficulty in the maintenance of the pregnancy, e.g., vaginal
bleeding, and thus serve as supporting evidence of reproductive dysfunction in the methanol-
exposed females. There were no reports of ultrasound confirmation of placental separation this
study. The lack of a monotonic concentration-response trend in the pregnancy duration data does
not nullify the fact that all of the methanol-exposed groups, both when tested collectively and
separately against controls, had significantly shorter pregnancy lengths. In sum, the reduction in
pregnancy duration observed in this study appears to constitute an adverse reproductive effect
associated with methanol vapor concentrations of 200–1800 ppm (260–2300 mg/m$^3$). The
incidence of a wasting syndrome in 2 females of cohort 1 in only the high dose group in the
absence of clinical pathology is significant; however, this effect was not observed in the second
cohort of animals tested. These effects in the high dose group may provide some assurance that a
maximally tolerated dose was achieved in this study design.

The HEI review committee noted that the maternal blood methanol level in the 200 ppm
(260 mg/m$^3$) group was only slightly higher than that of controls. But as the Committee also
acknowledges, "These results may indicate sensitivity to even small increases in maternal blood
methanol, or they may indicate random findings" (p. 130 of report). Indeed, without a better
understanding of the fetal pharmacokinetic and pharmacodynamic processes that could have been
involved in these effects, it may be presumptuous to suppose that the measured maternal blood
methanol levels are an adequate indicator of fetal exposure to the responsible toxic agent. In sum,
the HEI Committee’s notes of caution do not warrant dismissal of the reproductive and
developmental findings. One could conclude that these findings provide evidence of
developmental neurotoxicity in infant monkeys that had been exposed prenatally to methanol via
their mothers’ exposure to concentrations of 200–1800 ppm (260–2300 mg/m$^3$) methanol vapor
and possibly lower. This study does not address the issue susceptibility due to folate deficiency
and cannot address the issue of increase risk to the offspring.

Two other panel members came to the following conclusions about the utility of developmental
and/or reproductive findings:

The Panel had confidence in these data, and found them relevant to the consideration of human
reproductive risk. The non-dose related reduction in gestation length lacked concomitant
increases in adverse clinical signs or evidences of prematurity in the infants, suggesting that the
reduced length was not clinically relevant. Overall, the Panel believes that the data do not
indicate that methanol is a female reproductive toxicant in female macaques.
Reynolds et al. (97) conducted an aspartame feeding study in infant monkeys that pertains to methanol toxicity, since 10% of aspartame by weight is hydrolyzed to methanol in the gut (2). Four 17–42-day old Macaca arctoides monkeys/group (from Biologic Resources Laboratory) were fed formula with 0, 1,000, 2,000, or 2,500–2,700 mg aspartame/kg bw/day for 9 months. The doses would result in exposure to 0, 100, 200, or 250–270 mg methanol/kg bw/day according to Kavet and Nauss (2). The solubility limit for aspartame was reached at the highest dose level and bottles had to be shaken in order to keep the aspartame in solution. Both formula only and phenylalanine in formula were used as controls and additional water was available at all times. Equal numbers of male and female infants were not included in each group because the monkeys were assigned to groups as they were born; the ratio of male to female monkeys was about 3:1. Water and formula intake rates were monitored and it was found that water intake was increased in the highest dose group during the 3rd, 5th, 8th, and 9th month of exposure. Exposure to aspartame had no effect on growth as measured by body weight gain and crown-heel length. Developmental milestones such as teething, vocalization, alertness, tractability, or general behavior were also unaffected by treatment. A limited number of hematological (hematocrit, hemoglobin, white and red cell counts), serum chemistry (sodium, potassium, chloride, osmolality, and glucose) and urinalysis (pH, blood, protein, glucose, ketones, and bilirubin) parameters were measured at about every 2 months and were found to be unaffected in exposed groups. Electroencephalograms (EEGs) were obtained prior to exposure and at 4 and 9 months of treatment in all animals and at 4-month intervals after exposure in a total of eight animals. Treatment had no effect on EEGs. At about 1½ years of age, the monkeys were tested for learning performance and hearing ability by Suomi (98). Types of learning test included object discrimination, pattern discrimination, learning set discrimination, and oddity learning set discrimination as assessed in a Wisconsin General Test Apparatus. Orienting toward a sound was also tested. Data from learning tests was evaluated by ANOVA. Dietary aspartame exposure had no effect on learning performance or hearing ability. Learning performance in all groups was consistent to that reported by other laboratories for normal macaques at comparable ages in all groups.

Strengths/Weaknesses: A strength of the studies by Reynolds et al. (97) and Suomi (98) (involving 4 monkeys in each of 5 groups) is the employment of measures of known validity and sensitivity to neurotoxicant exposures. The data are clear, and the studies were accomplished in a rigorous manner. A clear strength of the studies was the inclusion of optional water so that diet was not a forced choice. In addition, animals were randomly assigned to groups as they were born. Several strengths were noted in the portion of the study conducted by Dr. Suomi. Although training monkeys to perform the tasks is difficult, Dr. Suomi’s staff did an excellent job in all aspects of this research. The monkeys learned the tasks, indicating that appropriate behavioral change could be obtained under the current conditions. The number of animals was adequate to reach the conclusions that Dr. Suomi made, as much larger numbers would be required to determine if an aberrant monkey was truly affected.

A limitation in study design is that the statistical power of the hypothesis tests is unclear, as no calculations are presented. The studies did not find any effects at the doses used. To the extent that these were pre-subscribed dose parameters, one could not then say that this was a weakness of the studies. However, in a study design sense, the studies are flawed because the only useful information to come from them is that the highest dose APPEARS to be tolerated. The studied should have continued to higher doses, and in the view of this reviewer, if doing so required alternative routes of administration the effort would have been worth it.

Utility (adequacy) for CERHR evaluation process: This study, as well as the assessments subsequently carried out on the subjects by Suomi (98), indicate that aspartame, at doses of up to
2.5–2.7 mg/kg/day or phenylalanine at 1.65 mg/kg/day for 9 months early in life, do not result in significant effects on a variety of indices of growth, development, and learning in *Macaca arctoides*. The results reasonably rule out the possibility that the aspartame/phenylalanine doses employed have very large effects on the endpoints assessed, but what is unclear is the effect size with which the data are compatible. The NOAEL was the highest dose of aspartame tested which represented 250–270 mg/kg bw/day of methanol.

3.2.3 Mechanisms of Toxicity

Bolon et al. (99) conducted a series of experiments in Crl: CD-1 ICR BR mice to determine the phase-specific developmental toxicity of methanol inhalation. In various experiments, mice were exposed to methanol vapors (HPLC grade) or HEPA-filtered air for 6 hours/day during either the period of organogenesis (gd 6–15), neural tube development and closure (gd 7–9), or potential and abnormal neural tube reopening (gd 9–11). The methanol doses were based on doses producing teratogenicity in previous rodent studies such as Rogers et al. (83). Methanol concentrations inside exposure chambers were verified. Dams were sacrificed on gd 17 and implantation and resorption sites were evaluated. In all studies fetuses were examined for external abnormalities, sexed, and weighed. Nonparametric tests were used for statistical analysis and the litter was considered the experimental unit. In addition to the discussion of these studies below, Tables 7.3-J, 7.3-K, and 7.3-L list the incidence and statistical significance of developmental effects.

In the pilot study, groups of 5–17 dams were exposed to 0 or 10,000 ppm methanol on either gd 6–15, gd 7–9 or gd 9–11 (Table 7.3-J). Major developmental effects were seen on gd 6–15 and included reduced fetal body weight, resorptions, neural tube defects, cleft palates, and digit defects. The same effects were noted on gd 7–9 with the exception of reduced fetal weight and digit defects. Cleft palate and digit defects were the only effects noted on gd 9–11.

Bolon et al. (99) next studied the dose response relationship for neural tube defects by exposing 20–27 mice/group to 0, 5,000, 10,000, or 15,000 ppm methanol on gd 7–9 (Table 7.3-K). In this study, fetuses fixed in Bouin’s solution were examined for visceral malformations. Resorptions and dilated renal pelves were noted at all dose levels. Developmental effects in the gd 7–9 group were consistent with the pilot study with exposure to 10,000 ppm and higher resulting in neural tube defects, cleft palates, and eye and tail defects and hydronephrosis. A reduction in fetal body weight and live fetuses/litter was observed in the 15,000 ppm group. In this study a group of 17 mice were also exposed to 15,000 ppm methanol on gd 9–11 to confirm the lack of neural tube effects observed in the pilot study. Maternal signs of intoxication (ataxia, circling, tilted heads, or depressed motor activity) were consistently noted following exposure to 15,000 ppm, but there were no effects on bodyweight when correct for gravid uterus weight. Developmental effects were consistent with the pilot study with fetuses showing cleft palate, limb and tail defects, renal pelvis dilation and hydronephrosis.

Bolon et al. (99) conducted a third experiment to better define the window of susceptibility for neural tube effects (Table 7.3-L). Mice (8–22/group) were exposed to 15,000 ppm methanol on gd 7, 8, 9, 7–8, 8–9, or 7–9. The key time period for neural tube defects was gd 7–8. Neural tube defects were observed with all combinations of exposure days containing gd 7 and 8 and were not observed following exposure to gd 9 only. Resorptions were increased on any combination of exposure days that included gd 7. There were no resorptions observed following exposure on gd 8 or 9.

Following evaluation of all study results, the authors noted that methanol exposure during gd 7–9 causes neural tube (exencephaly most common) and eye defects and exposure on gd 10–12 results
in limb defects. Hydronephrosis and cleft palate occurred following exposure during either time period. Malformations were sex specific with a greater incidence of neural tube defects and cleft palates in females and hydronephrosis in males.

**Strengths/Weaknesses:** Strengths in study design included exposure throughout organogenesis as well as for shorter periods to determine phase specificity, adequate sample size for final study, good animal husbandry, carefully controlled methanol exposures, reporting of methanol purity, dose-response information, examination of embryotoxicity at different gestational days of exposure, and pathologic documentation of embryo defects.

Limitations in study design included no dose-response information for gd 6–15 exposure, no skeletal exams, no dosimetry, and no information provided on plasma methanol concentrations.

**Utility (adequacy) for CERHR evaluation process:** The Panel has high confidence in these data for delineation of critical periods of exposure following high-dose inhalation of methanol. They noted that the pilot study and final study were in agreement. However, the relevance for humans is questionable because of the high exposure doses, especially the 10,000 ppm and 15,000 ppm concentrations needed to cause embryotoxicity. The Panel expressed concern about the 15,000 ppm data (on which much of the paper is based) because of the maternal toxicity observed in about 20% of the animals at this exposure concentration. Lack of skeletal examination also weakens interpretation. In addition a NOAEL was not identified for the gd 7–9 exposure.

A phase specificity study was also conducted in Crl: CD-1 mice by Rogers and Mole (100) in order to determine sensitive periods of developmental toxicity. Groups of 12–19 timed pregnant mice were exposed to filtered air or 10,000 ppm methanol vapors (Fisher Scientific Optima Grade) for 7 hours/day on gd 6–7, 7–8, 8–9, 9–10, 10–11, 11–12, or 12–13. The doses were based on those producing malformations in previous studies by Rogers et al. (83). Maternal blood methanol levels peaked at 4.0 mg/ml (125 mM) one hour after the end of the gd 7 exposure and returned to baseline levels 19 hours following exposure. Nine to 17 litters were examined per group with dams and litters considered the statistical unit. Statistical analysis included the General Linear Models procedure and multiple t-test of least squares method for continuous variables and the Fisher’s exact test for dichotomous variables. Examination of fetuses was limited to body weight measurements and observations for external and skeletal malformations. The skeletal exam was conducted by placing fetuses in 70% ethanol, macerating in 1% KOH, and staining with Alizarin red S. An increase in prenatal mortality only occurred following exposure on gd 6–7 or 7–8. The incidences of fetal malformations/exposure day and their statistical significance are listed in Table 7.3-M. Exencephaly was observed with exposures on gd 6–9 with the highest incidences occurring with gd 6–7 exposure. The incidences of cleft palate peaked after exposure on gd 7–8. A significant percentage of cleft palates were also observed in the gd 6–7 group and low numbers of fetuses were affected after exposure up to gd 11–12. The greatest number of exoccipital bone and axis and atlas vertebrae defects occurred with exposure on gd 6–7. With the exception of atlas defects following gd 7–8 treatment, very few vertebral defects were noted when exposures were conducted after gd 7. Increased numbers of presacral vertebrae were also noted in the gd 7–8 group. Cervical ribs peaked with exposures on gd 6–7 but were also observed with gd 7–8 exposures. In contrast, the greatest incidence of lumbar ribs was noted with exposure on gd 7–8 and significant increases were also observed on gd 6–7, 8–9, and 10–11.

As part of the same study, Rogers and Mole (100) examined the phase specificity in CD-1 mice exposed to 10,000 ppm methanol vapors for 7 hours on either gd 5, 6, 7, 8, or 9. A total of 12–17
litters/exposure day were evaluated. Fetal malformation results are listed in Table 7.3-N. Gd 7 was the most sensitive time period for the majority of fetal effects as observed by the highest incidence of resorptions, exencephaly, cleft palates, axis vertebrae defects, and cervical and lumbar ribs. Exoccipital malformations and reduced numbers of presacral vertebrae were noted at the highest frequency on gd 5. The highest occurrences of atlas vertebrae malformations were seen on gd 5 and 6.

The study authors noted that the occurrence of exencephaly coincided with treatment during the period of neurulation and neural tube closure. However the incidence of cleft palates peaked following exposure prior to the period of palatal development. Cleft palate and exencephaly appeared to be competing malformations because the two malformations rarely occurred in the same fetuses. Some malformations (digit defects and hydronephrosis) observed in a study of mice by Bolon et al. (99) were not repeated in this study. Authors concluded that methanol exposure is most toxic during the gastrulation and early organogenesis stages. Skeletal defects suggest vulnerability to segmentation of the anterior region of the embryo.

A summary of the phase specification studies by Bolon et al. (99) and Rogers and Mole (100) is included in Table 7.3-O.

**Strengths/Weaknesses:** Strengths of study design included exposures that were well-characterized, and characterization of plasma methanol levels over several time points during the course of the day 7 exposure. Although chamber concentrations were not reported, previous work with the same chambers demonstrated a highly stable atmosphere. Statistical analyses for the 2-day exposure periods were appropriate.

Weaknesses in study design included evaluation of small numbers of litters (n=12–14) for most critical periods, measurement of plasma methanol levels only on gd 7, recording of only skeletal and external findings, no statistical comparisons reported for single day exposures, and single day exposures at only a single concentration (10,000 ppm). The single concentration was quite high, resulting in maternal toxicity at certain intervals and not providing information regarding interval-specific dose response patterns.

**Utility (adequacy) for CERHR evaluation process:** The Panels confidence in this data is moderate to high. It provides valuable information regarding periods of sensitivity for critical developmental toxicity at a single high exposure level. The Panel noted that the number of resorbed/dead pups per litter was highly variable, possibly obscuring small effects on pup mortality. The usefulness of this study for human evaluation is questionable.

Bolon et al. (101) conducted additional studies in Crl:CD-1 ICR BR (CD-1) mouse embryos and fetuses to identify the scope of methanol-induced cephalic malformations and to identify target sites in neurulating embryos. In an experiment to identify fetal pathology, 20–25 dams were exposed to 0 or 15,000 ppm methanol vapors for 6 hours/day from gd 7–9 and were sacrificed on gd 17. As previously observed, methanol-treated dams were intoxicated. Fetal malformations were consistent with those previously observed by Bolon et al. (99) and Rogers et al. (83). Cephalic neural tube defects affected about 15% of fetuses. Exencephaly was the most common neural tube defect and was usually accompanied by malformed or missing cranial bones and eye anomalies (open eye, cataracts, and retinal folds). Malformations occurring at lower frequencies included anencephaly, encephaloceles and holoprosencephaly. Bolon also measured the thickness of fetal frontal cortices, an endpoint that was not examined in previous studies. A total of 16–24 litters and 39–56 fetuses/group were examined. The data was analyzed by ANOVA with the individual animal as the unit. Significant reductions in frontal cortex thickness occurred.
in all methanol-treated litters, including litters with overtly normal fetuses. Individual layers of the cerebral cortex were affected as noted by reductions in intermediate cortex/subventricular plate and cortical layer 1 thickness but an increased neuroepithelium thickness. An apparent increase in subventricular plate cellularity was also observed. Although the biological significance of changes in cortical thickness is not known, the observation led the authors to conclude that pathology may remain in older conceptuses in the absence of gross lesions and that looking at gross lesions alone may underestimate toxicity.

In the study of embryonic pathology, Bolon et al. (101) exposed the dams to air or 15,000 ppm methanol vapors for 6 hours/day from gd 7–8 or gd 7–9. Dams exposed on gd 7–8 were sacrificed on gd 8.5 and 9.0 (n=3–5 group/day) and dams exposed on gd 7–9 were on sacrificed on gd 9.5 and 10.5 (n=4–9/group/day). Gross, histological, and morphometric evaluations were conducted on embryos. Data were evaluated by the Mann-Whitney U-Test with the litter as the unit for dead and malformed fetuses and the embryo as the unit for cell density and mitotic index. At each sacrifice period, delays in growth and rotation and microcephaly were observed in treated embryos. The percentages of treated embryos with neural tube defects were 41 and 28% on gd 9.5 and 10.5 respectively and the percentages were significant compared to controls. Study authors noted that the incidence of neural tube defects in gd 9.5 embryos was 3 times higher than the incidence in gd 17 fetuses in a previous study (99) and postulated that less severe lesions may be repaired later in development. On gd 8.5 and 9, cephalic neural fold margins were swollen, blunted, and poorly elevated in the treated group. Consistent and severe reductions in the quantity, cell density, and mitotic index of cranial mesoderm was noted for each gestation day. Reduced proliferation and mitotic index was observed in the neuroepithelium. Decreased quantity and abnormal presence of neural crest cells in the folds dorsal to the foregut were also noted. These effects led authors to conclude that neural tube defects were apparently caused by permanent patency of the anterior neuropore due to an inability to raise the neural folds. Authors identified the neuroepithelium, neural crest, and mesoderm as the likely targets of methanol.

Strengths/Weaknesses: The strengths of study design include a thorough pathological examination at term and pathogenesis after exposure, good animal husbandry, well controlled exposures with documentation of chamber concentrations of methanol, reporting of methanol purity, and excellent pathology and histopathology to document lesions.

A limitation of the study is that only a single, high exposure level which caused maternal intoxication was studied. Although the number of litters examined at each timepoint was small (3-5 for control and 4-9 for treated groups), a large number of embryos was examined histopathologically at each time point. How embryos from a litter were divided for different analyses was not stated. Although appropriate statistical tests were done, the embryo, rather than the litter, was used as the experimental unit for examination of cortical thickness, cell density and mitotic index.

Utility (adequacy) for CERHR evaluation process: The utility of this study for understanding the pathogenesis of fetal neural defects is moderate to high. In addition to confirming previous findings, it demonstrates effects on neuroepithelium at the histological level. The study indicates putative mode of action (reduced proliferation) and targets (neuroepithelium, mesoderm, neural crest). The relevance to humans may be very limited because of the high-dose exposure scenario.

Connelly and Rogers (102) conducted a study to determine if methanol induced alterations in cervical vertebrae result from homeotic shifts in segment identity and/or patterning. A homeotic transformation is the development of one structure in the likeness of another. For example, a vertebra could assume the phenotype of a vertebra in front of (anteriorization) or behind it.
(posteriorization). A homeobox gene family controls developmental patterning and mutations in these genes can produce homeotic transformations. To study this mechanism, 6–7 Crl:CD-1 mice/group were gavaged with methanol [purity not specified] in distilled water twice daily on gd 7 at 0 (distilled water), 2,000, or 2,500 mg/kg bw for a total dosage of 0, 4,000, or 5,000 mg/kg bw. Doses were based on past studies by Rogers et al. (83). On gd 18, the dams were sacrificed and fetuses were examined for vertebral alterations according to methods described above in the summary for the Rogers et al. (83) study. Data were evaluated with contrast t-tests of least square means within ANOVA with the dam and the litter as units of comparison. Observations that were consistent with homeotic transformations included ribs on cervical vertebra 7 (C7), tuberculum anterior on C5, and splits in C1 and C2; the effects were statistically significant at the high dose. The frequency of these vertebral effects are listed in Table 3-2. In an examination of disarticulated vertebrae, distinguishing characteristics were seen on vertebrae anterior to those normally displaying that characteristic. The authors concluded that methanol can alter segment patterning in mouse embryos, resulting in posteriorization of cervical vertebrae.

Strengths/weaknesses: A strength of this study is that skeletal malformations were more thoroughly examined than is generally done in developmental toxicity studies. In addition, the statistical analyses were adequate.

The limitation of this study is that small numbers of animals were used per group. Blood methanol levels were not measured.

Utility (adequacy) for CERHR evaluation process: The Panel’s confidence in these data are low to moderate. The authors have demonstrated skeletal malformations similar to those previously observed (83), but it is not quite clear how these data fit into the overall picture of methanol-induced developmental toxicity. This is another study that provides information on mechanisms of high-dose toxicity in rodents. The panel will need to discuss the relevance to the human situation.

Dorman et al. (54) conducted a series of experiments to examine the role of formate in methanol-induced exencephaly in Crl: CD-1 ICR BR (CD-1) mice. Their studies were a sequel to the studies of Bolon et al. (99, 101) that delineated the critical period of methanol-induced exencephaly. The Dorman et al studies routinely determined methanol and formate levels in
maternal blood and decidual swellings. Dams treated with methanol were killed on gd 10 while
formate treated dams were killed on either gd 10 or 18. Controls were included as appropriate for
the experimental design. HPLC grade methanol was used. Statistical significance for in vivo
studies was conducted with one-way ANOVA and then Fisher’s least significant differences test
when F ratio indicated statistical significance. Dams (n=12–14/group) exposed to 10,000 ppm
methanol for 6 hours on gd 8 had litters with statistically significant increases in open neural
tubes. Pretreatment of dams with 4-methylpyrazole (4-MP) prior to methanol exposure to inhibit
metabolism by alcohol dehydrogenases produced a numerical, but not statistically significant,
increase in the number of litters with open neural tubes. Treatment with 4-MP had no significant
effect on end-of-exposure decidual swelling or maternal plasma methanol concentrations or peak
blood or decidual swelling formate concentrations. Methanol levels in saline and 4-MP treated
animals respectively were 65 and 75 mM in maternal plasma and 83 and 62 mmole/kg in decidual
swellings. Formate levels in decidual swellings were not altered and were in the range of 1.8 to
2.1 mmole/kg. However, treatment with 4-MP modified methanol metabolism as evidenced by
an increased 24 hour maternal plasma methanol area under curve value (AUC) of 1,190 versus
990 mmoles/hour for controls and 4-MP groups, respectively. Decidual swelling AUC values
were unaffected (1,110 and 1005 mmoles/hour/kg) for control and 4-MP, respectively. Six hour
exposure to 15,000 ppm methanol on gd 8 increased end of exposure methanol concentrations to
223 mM and 147 mmole/kg in maternal plasma and decidual swelling, respectively. AUC values
for these samples were 2,860 mM/hour and 2,130 mM/hour/kg. As was observed at the 10,000
ppm study there was no statistically significant increase in any formate levels after 15,000 ppm
exposure.

In the same study, Dorman et al. (54) compared maternal blood and decidual levels of methanol
and formate in mice that received a single 1,500 mg/kg bw gavage dose of methanol in water on
gd 8, with or without pre-treatment with 4-MP. As observed with the inhalation study, treatment
with 4-MP increased the 24 hour methanol AUC value in maternal plasma and decidua, but had
no effect on peak maternal blood or decidual levels of methanol or formate. Maternal blood and
decidual levels of methanol peaked at about 1 hour following gavage. Methanol levels in saline
and 4-MP treated animals respectively were 50.3 and 45.2 mM in maternal plasma and 33.3 and
20.4 mmole/kg in decidual swellings.

Dorman et al. (54) continued to study the role of formate in methanol-induced developmental
toxicity by examining neural tube formation and embryo/fetal growth following gavage of dams
with sodium formate in water at 0 or 750 mg/kg bw on gd 8. This formate dose mimics a
maternal pharmacokinetic profile that is observed during a 6 hour, 10,000 ppm methanol vapor
exposure. The peak maternal plasma and decidual formate levels were 1.05 and 2.0 mM/kg,
respectively. Embryos or fetuses were examined following sacrifice at either gd 10 or gd 18.
Exposure to formate did not increase the incidence of open neural tubes or adversely effect fetal
growth at either timepoint.

Using different concentrations of either methanol or formate, Dorman et al. (54) investigated
dysmorphogenesis in the in vitro culture of 7 and 8 day old embryos. A more detailed description
of this study is included later in this section where the other in vitro studies are described. They
observed a concentration dependent increase in prosencephalic lesions and branchial arch
hypoplasia with methanol at 250 mM and prosencephalic lesions, cephalic dysraphism and
branchial arch hypoplasia with methanol at 375 mM and formate at 40 mM; statistical
significance was achieved from stage-matched controls. Noting the limited metabolic capacity of
isolated embryos in culture the authors assert that their findings provide strong evidence that
methanol can act as a direct chemical teratogen.
**Strengths/Weaknesses:** This is an important series of experiments designed to investigate the role of methanol metabolites in inducing exencephaly. The investigators had extensive experience with the mouse model of methanol-induced teratogenicity and thus were able to pinpoint critical periods to examine. In this case the use of a high dose of methanol is not a defect because this is the dose that had previously been established to produce reproducible effects. These studies were innovative and well-designed. Strengths of study design included adequate numbers of animals/embryos per group, stable, well-controlled exposure, reporting of methanol grade, measurement of blood formate and methanol, and appropriate animal husbandry. The studies used *in vivo* and *in vitro* (discussed below) routes of exposure and compared metabolism inhibitor data with exposure to oral formate.

Appropriate statistical analyses were performed; however, it was not stated if the litter was used as the experimental unit for the *in vivo* studies.

**Utility (adequacy) for CERHR evaluation process:** These data are of high utility for defining the proximate developmental toxicant following methanol exposure in mice. The observation that the parent compound (administered at high concentrations) and not formate is responsible for methanol-induced exencephaly is noteworthy. The authors also noted that the *in vivo* and *in vitro* doses associated with these effects produce symptoms of clinical intoxication or delayed embryo growth. Given what is known about saturation of methanol metabolism under high exposure conditions, the relevance of the high-dose rodent developmental studies for human risk assessment is uncertain and needs careful consideration by the Expert Panel.

Sakanashi et al. (70) conducted a study to determine the effects of maternal folic acid intake on methanol-induced developmental toxicity in mice. Commencing 5 weeks prior to mating and throughout the entire study, Crl: CD-1 mice were fed a purified, amino acid-based folic acid-free diet fortified with either 400, 600, or 1200 nmol/kg diet folic acid. The author described the 3 diets as containing low, marginal, and adequate folate levels, respectively. All diets contained 1% succinylsulfathiazole to prevent endogenous synthesis of folate by intestinal flora. On gd 6–15, mice were gavaged twice daily with water or methanol [purity not specified] in water at 2,000 or 2,500 mg/kg bw for a total daily dose of 0, 4,000 or 5,000 mg/kg bw. The original methanol dose of 4,000 mg/kg bw/day was based on the work of Rogers et al. (83) that observed significant developmental abnormalities. The dose of methanol was increased to 5,000 mg/kg bw/day after results of a pilot study indicated that the frequency of malformations under their experimental regimen was less than that reported by Rogers et al. Dams were sacrificed on gd 18 and parameters standard in a Segment II developmental toxicity protocol were assessed as listed in Table 7.3-P. Three to 29 litters were examined per group. Skeletal data were analyzed with a general linear model using percent affected/litter. For continuous variables, the dam and litter were considered units of comparison and data were evaluated by 2-way ANOVA and Fisher’s protected least significant difference test. Incidence of abnormalities as percentage of affected litters were analyzed using binomial statistics.

The authors concluded that the level of induced folate deficiency in their study was not severe. After 5–7 weeks on their respective diets, body weights of mice were similar and they presented no external evidence of deficiency. Maternal hematocrit and plasma folate levels were not affected by level of folic acid, but liver folate levels in the 400 nmol/kg group were decreased compared to the 600 or 1200 nmol/kg groups (p = 0.06). Pregnancy rate was similar across the folic acid groups. Gestational bodyweight gain, number of implantations, and number of live pups/litter were decreased in the dietary group that received 400 nmol folic acid/kg diet. An increase in the litter incidence of cleft palate in the 400 nmol/kg folic acid group was reported by
the authors. [However, the Expert Panel did not agree that reduced folic acid intake had an affect on cleft palate due to a lack of statistical significance].

Methanol treatment decreased gestational weight gain in groups fed diet containing 600 or 1200 nmol folic acid/kg diet; these effect were not seen in the 400 nmol/kg group. Methanol did not affect pregnancy or implantation rate. There was no consistent effect of methanol exposure on hematocrit or liver folate level; plasma folate was increased in mice from the 1200 nmol/kg group that received 5,000 mg/kg/day methanol. Methanol decreased fetal body weight in each of the folic acid dietary groups. An increase in the litter incidence of cleft palate was seen with methanol treatment in all dietary groups; the incidence was exacerbated in the 400 nmol/kg group. The litter incidence of exencephaly was increased by exposure to methanol in the 400 nmol folic acid/kg group. Methanol increased anomalies affecting the cervical region although the incidence tended to decrease in dietary groups receiving larger amounts of folic acid.

The authors concluded the developmental toxicity of methanol was enhanced when maternal folic acid stores were low. They speculate that their data support a role for formate in the effects observed.

Strengths/Weaknesses: This study had adequate numbers of animals in all groups except the group fed 400 nmol/kg folic acid and exposed to 4,000 mg/kg bw/day methanol. Statistical analyses were adequate. Maternal liver folate levels were dramatically decreased in mice eating the 400 nmol folic acid/kg diet. Although the reproductive aspects of this study are well designed, there are limitations with the nutritional aspect of the study design. A common outcome of vitamin deprivation is loss of appetite and reduced food intake. Therefore, in studies of this type pair-fed animals are generally included. The pair-fed control animals are fed a normal diet but in amounts equivalent to their vitamin-deficient counterparts. This insures equivalent consumption of calories and other nutrients. Without such controls there is a question whether the observed effects are due to folate deficiency, general malnutrition, or some other nutrient deficiency. As indicated in Figure 1 of the study, the animals fed low folate diets gained less weight during gestation; therefore other nutrient deficiencies were probably present. For these reasons this study has limited value for evaluating the influence of maternal folate status on methanol developmental toxicity. In addition, folate determinations were done only one time and three days after the last methanol dose; if methanol had an effect on folate levels, there may have been time for recovery. Only maternal folate was determined; it is not clear if either the folate deficiency or methanol affected fetal folate levels. Since total folate was determined, it is not possible to determine if there may have been alterations in the folate subtypes present. Even at the lowest folic acid concentration, there was no difference in plasma folate level. It is also not clear if the diet was removed from the dams prior to sacrifice; plasma folate levels are sensitive to food consumption so if the chow was not removed, the animals may have eaten close to the time of sacrifice which may account in part for the lack of effect on plasma folate concentrations. The low folic acid group treated with 4,000 mg/kg bw/day of methanol had only three litters analyzed and methanol purity was not reported.

Utility (adequacy) for CERHR evaluation process: The Panel’s confidence in this study is moderate. The possibility of a contribution to methanol toxicity by a nutritional effect other than folate deficiency was not controlled for in the study. The lack of effect on plasma folate levels by the various folic acid deficient diets is somewhat troublesome, but this may have been due in part to the length of time between the animals’ final meal and sacrifice. Plasma levels are very sensitive to food consumption, making them an insensitive indicator of tissue folate status which is more stable over time. Maternal hepatic folate levels were greatly reduced by the 400 nmol/kg folic acid diet, and hepatic levels may be the best measure of tissue folate status.
Fu et al. (67) performed studies in Crl: CD-1 mice to determine whether methanol influences maternal or fetal folate concentrations and whether maternal reticulocyte micronuclei formation is a marker for folate deficiency or methanol toxicity. The dietary and mating aspects and data analysis methods of this study are similar to those described above in Sakanashi et al (70). In the Fu et al study the amino acid-based folic acid-free diet was supplemented with either 400 or 1200 nmol folic acid/kg diet and 1% succinylsulfathiazole. The authors stated that the diets contained marginal and adequate folic acid supplementation, respectively. Methanol (HPLC grade) was administered on gd 6–10 in water at a dose of 0 or 5,000 mg/kg bw/day given in two divided doses. Evaluations of dams and fetuses were conducted following sacrifice on gd 18; 21–24 litters/group were examined. Despite the shorter exposure period in this study, effects on fetal growth, survival, and external malformations were consistent with those reported by Sakanashi et al. (70). Table 3-3 lists selected study results as a function of different dietary folate levels and methanol exposure. Folate levels in fetal liver, and in maternal plasma, liver, and erythrocytes were lower in mice on a 400 nmol folic acid/kg diet with and without exposure to methanol. Methanol treatment did not produce a further reduction of folate levels in maternal or fetal liver or maternal red blood cells. Neither folate intake nor methanol exposure affected the incidence of micronuclei formation in maternal reticulocytes, as described in Section 2. The study authors concluded that fetal folate stores were reduced despite a lack of overt signs of maternal folate deficiency and it appears that fetuses do not have preferred access to maternal folate stores. They also noted that folate levels were measured 8 days after methanol exposure ended and speculated that folate levels may have been lower during methanol exposure.

Table 3-3. Effects of Dietary Folic Acid Intake and Methanol Exposure on Selected Maternal and Fetal Parameters, Fu et al. (67).

*Units not reported; units are most likely the same used in Sakanashi et al. (1996): nmol/g for liver and nmol/L for plasma.

**Units not reported.

Strengths/Weaknesses: The strengths of this study are that adequate numbers of animals were used, the grade of methanol was reported, statistics were adequate, and that folate reduction was achieved as determined by either hepatic, erythrocyte or plasma levels in mice fed 400 nmol folic acid/kg diet. Measured fetal hepatic folate levels were also reduced.

The principal weakness in study design is that folate analyses were performed 8 days after the last methanol dose. It is not clear why the plasma folate levels differ between this study and that of Sakanashi et al., (70); the method of analysis appears to be different in the two studies which may account of some of the difference. Also, the time interval between the final methanol dose and the measurement of plasma folate was much longer in this study (8 versus 3 days). Food consumption was not monitored, but it is possible that the animals in the 400 nmol/kg folic acid
group may have consumed more chow after methanol treatment leading to less of an effect on plasma methanol levels (55% decrease compared to 1,200 nmol/g folate diet in Sakanashi et al. study versus 30% decrease in present study). The same criticism (lack of pair-fed controls) that were discussed for the Sakanashi et al. (70) study apply to the Fu et al. study (67).

Utility (adequacy) for CERHR evaluation process: The Panel’s confidence in these data is moderate. Length of exposure was altered from the earlier study (70). The oral dose used in this study is similar to 10,000 ppm inhalation dose as determined by the severity of the defects observed. The level of hepatic folate deficiency achieved was very similar to that achieved with the 400 nmol dose of folate in the Sakanashi et al. study (62% decrease compared to adequate folate level in Sakanashi study versus 51% decrease in current study). However, there are quantitative, although not qualitative, differences in the results between this study and the earlier study of Sakanashi et al. Cleft palate and exencephaly were still the most common abnormalities observed. In the earlier study, folate deficiency produced neither cleft palate nor exencephaly in the absence of methanol; in the current study, cleft plate was significantly increased by folate deficiency. Exencephaly was also increased, but this difference was not statistically significant due to the presence of a fetus with exencephaly in the 1,200 nmol folic acid/kg diet–water group. Although methanol increased the incidence of exencephaly in the 400 nmol folate/kg diet group, this difference was not statistically significant due to the high incidence of exencephaly in the 400 nmol folate/kg diet – water group; methanol had significantly increased the incidence of exencephaly in the Sakanashi et al. study. The lack of pair-fed controls severely limits evaluation of the role of folate in methanol-induced toxicity.

De-Carvalho et al. (103) conducted a study to determine if methanol-induced fetotoxic effects in rats are altered by malnutrition. One group of pregnant Wistar rats (FIOCRUZ breeding stock) was fed ad libitum (well-nourished group) and a second group (protein-calorie malnourished group) received half the amount of diet consumed by the well nourished group. On gd 6–15, rats in each dietary group (n=10–17/group) were gavaged with distilled water or methanol [purity not specified] at 2,500 mg/kg bw/day. Dams were sacrificed on gd 21. Dams in the malnourished groups gained less weight (corrected and uncorrected for gravid uterus) and liver weight was reduced. Methanol treatment further reduced weight gain in malnourished dams only during the treatment period but had no effect on liver weight. Evaluation of fetuses (n=78–116/group) was limited to mortality, bodyweight, external malformations, and skeletal malformations. After fetuses were preserved in 5% formalin, skeletal abnormalities were observed by clearing the fetuses with KOH and staining with Alizarin Red S. Resorption data were analyzed by chi-square test and all other fetal data by one-way ANOVA. Adverse fetal effects and their statistical significance are listed in Table 7.3-Q. Malnourishment with or without methanol treatment resulted in reduced fetal weight and delayed ossification. Methanol treatment in malnourished dams potentiated delays in ossification but not reductions in fetal weight. Exposure to methanol resulted in decreased fetal weight and increased cervical ribs, regardless of nutritional status. Resorptions were increased in malnourished rats treated with methanol. Neither malnutrition or methanol exposure caused an increased in external malformations. The authors concluded that malnutrition has no effect on methanol-induced structural malformations, but that delayed ossification in malnourished rats is aggravated by methanol treatment.

Strengths/Weakness: The strengths of this study are that treatment occurred throughout gestation and generally an adequate number of animals was examined in each group.

Limitations in study design are that only one dose of methanol was used and this dose was administered once daily by gavage, methanol purity was not reported, the food deprivation was rather drastic, and visceral malformations were not examined.
Generally, appropriate statistical tests were done. However, the Fisher Exact Test should have been used rather than the chi-square test for numbers of 10-17. Additionally, it appears that the fetus, rather than the litter, was used as the experimental unit for the analysis of skeletal anomalies.

Utility (adequacy) for CERHR review: The Panel’s confidence in these data are low due to the study design (single oral dose administered once daily with no attempt to relate it to doses used in other studies as well as the rather drastic food deprivation). As indicated by the data in Table 1 of the study, these were severely malnourished animals. They had more than a 20 g loss in body weight compared with the 35 g body weight gain in the controls. The Panel could not see how these data would apply to any realistic human situation.

*In vivo* intrauterine microdialysis was used to measure methanol disposition in pregnant Sprague-Dawley rats (from Hilltop Laboratory Animals) on gestation day (gd) 20 after methanol administration by intravenous (iv) injection (100 or 500 mg/kg) or infusion (100 or 1,000 mg/kg/hr) in 3–4 rats/dose (53). HPLC-grade methanol was used and saline was used as the vehicle in these studies. Statistical analyses included one-way ANOVA, linear least-squares regression, and two-tailed Students t test. Maternal blood and intrauterine dialysate were analyzed for methanol. Also, pregnant rats on gd 14 or 20 and pregnant Crl: CD-1 mice (n=4–6/dose/species) on gd 18 received methanol (0, 100 or 500 mg/kg) and tritiated water by iv injection, then maternal blood and intrauterine dialysate were analyzed for radioactivity. Methanol significantly reduced the rate of radioactivity uptake into the fetus in a dose-dependent manner, suggesting an inhibition of uteroplacental blood flow. For gd 20 rats, iv administration of 100 mg/kg caused a 31% decrease in initial radioactivity uptake, and 500 mg/kg caused a 45% decrease. For gd 14 rats, the decreases in initial uptake for the two doses were 30 and 57%, respectively. In gd 18 mice, the rate of radioactivity uptake was also decreased by methanol in a dose-dependent fashion. Initial uptake rate was decreased 26% by 100 mg/kg, and 47% by 500 mg/kg. The authors hypothesized that part of methanol's embryotoxic effects may be due to hypoxia resulting from decreased blood flow to the conceptus. Short-chain alcohols are known to affect the cardiovascular system, and the fetal effects of methanol are similar to those known to result from hypoxia (cleft palate, decreased survival, vertebral and rib formation, decreased birth weight). However, other mechanisms may be at work as well, because methanol frequently induces exencephaly in rodent embryos, while maternal hypoxia itself rarely does.

Strengths/Weaknesses: This is technically a very sophisticated, well-done study that addresses an important issue — kinetics of methanol in the maternal-conceptual unit. The use of intrauterine dialysis to monitor blood flow is an impressive technique. In addition, the methanol grade was reported. Limitations are the high dose of methanol and the non-environmental exposure routes.

Utility (adequacy) for CERHR evaluation process: This study is useful for evaluating other rodent studies where high doses of methanol were employed. Under these exposure conditions, the reduction in maternal blood flow may contribute to the observed teratogenic effects in rodents. However, the results have not been reproduced under environmentally relevant exposure scenarios. Due to the doses used, administration as a bolus and route administered the utility of this study to predict human health risks is limited.
Toxicokinetic studies by Perkins et al. (49) and Ward and Pollack (48) provide some insight into possible mechanisms of toxicity. Additional details of both studies are included in Section 2.1.6 and 2.1.1.2, respectively. Perkins et al. (49) compared blood levels of methanol in female CD-1 mice and Sprague Dawley rats following an 8-hour exposure to methanol at 5,000, 10,000, and 15,000 ppm. At equivalent doses, methanol blood levels in mice (3,580, 6,028, and 11,165 mg/L) were about 3.5 times higher than in rats (1,047, 1,656, and 2,667 mg/L) despite the fact that the elimination rate of methanol in mice is about twice that of rats. Authors noted that higher blood methanol concentrations in mice versus rats may explain the increased sensitivity of mice to methanol-induced teratogenicity.

Ward and Pollack (48) compared the rate of methanol metabolism in liver homogenates from non-pregnant, pregnant (gd 20), and fetal CD-1 mice and Sprague-Dawley rats (n=4-5/group). The homogenates were incubated with 0.005–1.0 mg/L methanol for 40 minutes and metabolism was measured by the production of formaldehyde. The metabolic rate of mouse homogenates was about twice that of rat homogenates. In both mice and rats, the metabolic rate was about 15% lower in homogenates from pregnant versus non-pregnant animals and about 95% lower in homogenates from fetal versus adult animals. According to the study authors, these data suggest that the fetus does not significantly contribute to the elimination of methanol from the maternal-fetal unit. These results are consistent with an older study that found no or low (20% of maternal values) alcohol and aldehyde dehydrogenase activity in livers from 17 and 21 day Wistar rat fetuses. Essentially no activity was observed in placental tissue (104).

A series of in vitro studies were conducted to examine the embryotoxicity of methanol or its metabolites in the absence of confounding maternal factors.

Andrews et al. (105) conducted an in vitro methanol exposure study to compare methanol sensitivity in mouse versus rat embryos. Crl: Sprague-Dawley rat and CD-1 (Crl) mouse embryos were removed from pregnant dams during the stage of neural tube closure (gd 9 for rats and gd 8 for mice). Rat embryos (17–50/group) were incubated in serum containing 0, 2, 4, 8, 12, or 16 mg/ml methanol (0, 62.4, 125, 250, 375, 500 mM) for 24 hours. Mouse embryos (26–47/group) were incubated for 24 hours in serum containing 0, 2, 4, 6, or 8, mg/ml methanol (0, 62.4, 125, 187, or 250 mM). Rats but not mice were incubated in serum without methanol for another 24 hours. The dose level of 250 mM is approximately equivalent to maternal methanol serum concentrations in mice that inhaled 15,000 ppm methanol or rats that inhaled 20,000 ppm methanol for 7 hours (82, 83). At the end of the incubation period, the embryos were examined for viability and dysmorphogenesis. Growth and development were assessed by endpoints such as crown-rump length, head length, yolk sac diameter, somite number, developmental score and protein contents. In rat embryos significant developmental effects were first noted at 250 mM and included increased numbers of abnormal embryos and reduced growth. Increased embryolethality was noted at 375 mM and abnormalities in surviving embryos included open neural tubes and abnormal brain and limb bud development. Nearly complete embryolethality occurred at 500 mM. In mouse embryos, some significant signs of reduced growth and development were first noted at 62.4 mM. Embryolethality and an increased incidence of open neural tubes was noted at 187 mM and higher. The study authors concluded that mouse embryos have a greater intrinsic sensitivity to methanol than rat embryos because developmental effects occurred at lower doses in mice. Authors suggested that the effects were due to methanol and not its metabolites because constant levels of methanol over the exposure period suggested a lack of significant metabolism.
**Strengths/Weaknesses:** The strengths of this study are that doses used were similar to *in vivo* methanol levels after inhalation exposure and that length of exposure was the same for embryos of both species.

A weakness of this study is that different developmental stages were covered during the *in vitro* culture period for the two species. Although the exact developmental stages covered by the culture period were different for the two species, neural tube closure was completed in embryos of both species during the culture period.

**Utility (adequacy) for CERHR evaluation process:** The Panel’s confidence in these data is moderate to high. Outcomes of these in vitro studies were similar to those observed *in vivo*. This type of study insures that embryos of both species were exposed to the same concentrations of methanol for the same length of time, a situation that will probably not occur *in vivo* due to differences in pharmacokinetic and pharmacodynamic parameters in the two species. This is an important study because it suggests that the developmental effects associated with high-dose methanol exposures in rodents may be due to methanol, not formate. Unfortunately, the authors did not measure formate in the culture medium. They did, however, establish that there were no changes in methanol concentrations during the culture period. These results, together with those of Dorman et al. (54), point to methanol as being responsible for the dysmorphogenesis observed in rats and mice. This is most likely due to the accumulation of methanol under high-dose exposure scenarios.

Abbott et al. (106) conducted a study to further characterize methanol effects on rat and mouse embryos and determine if increased cell death occurs at sites with abnormal gross morphology. Gd 9.5 (0 somites) Crl: Sprague-Dawley rat embryos (n=4–5/group) were exposed to methanol at 0, 8, 12, or 16 mg/ml (0, 250, 375, or 499 mM) for 24 or 48 hours. Gd 8 (3 – 5 somites) Crl: CD-1 mouse embryos (n=17–18/group) were exposed to methanol at 0, 2, 4, or 8 mg/ml (0, 62.4, 125, or 250 mM) for 24 hours. The embryos were examined for viability and dysmorphogenesis as described in Andrews et al. (105). Results in rat and mouse embryos were similar to effects previously observed in this laboratory (105) and included reduced growth and development with increased numbers of abnormal embryos. Anomalies included erratic neural seam, open neural tube, and abnormal brain development. Again, mice were shown to be more sensitive than rats with significant adverse effects first noted at 250 mM versus 375 mM, respectively. Effects on growth and development were generally similar but more pronounced in rats exposed for 48 hours versus 24 hours. There was limited cell death noted in rat embryos exposed for 24 hours. However the 48 hour exposure to 499 mM methanol resulted in increased cell death in the forebrain, optic vesicle, visceral arches, and otic vesicle. Increased cell deaths also occurred in the same regions of mouse embryos exposed for 24 hours. Authors noted that cell death occurred in many regions that develop into structures (i.e., cranium, eye, ear, and cleft palate) displaying malformations following *in vivo* exposure. They also noted a lack of excess cell death in the neuroepithelium or neural folds, suggesting that neural tube defects occur through mechanisms other than cell death.

**Strengths/Weakness:** A strength of this study is that cell death was examined in addition to the usual endpoints.

A limitation of this study is that different developmental stages were covered by treatment in the two species. Although the exact developmental stages covered by the culture period were different for the two species, neural tube closure was completed in embryos of both species during the culture period. Small numbers of embryos were examined in some of the groups; it is not clear how many embryos were used for the analysis of cell death.
Utility (adequacy) for CERHR review: The Panel’s confidence in these data is moderate. The results observed in both species in this study are very similar to those reported by Andrews et al. (105) in both rats and mice increasing the confidence in the data. They observed cell death in control embryos that was enhanced by methanol treatment. The areas demonstrating cell death induced by methanol in this in vitro study were the same areas that were observed to be malformed following in vivo treatment with methanol (83). That suggests that the mechanism for these malformations may be increased cell death. Neural tube defects were observed in vitro, but increased cell death was not observed in the neuroepithelium or neural tube. The failure to find cell death in the neural tube region suggests that the failure of the neural tube to fuse may be occurring by a mechanism other than increased cell death.

Abbot et al. (107) extended the in vitro analysis of methanol induced developmental toxicity by examining cleft palates in cultures of Crl:CD-1 mouse embryo mid-craniofacial regions. Twelve-day-old embryos (n=20–44/group) were dissected and cultured in serum-free media containing 0, 6, 8, 10, 12, 15, 18, or 20 mg/ml methanol (0, 187, 250, 312, 374, 468, 561, or 624 mM). Methanol exposures lasted for 6 hours, 12 hours, 1 day, or 4 days and all explants were incubated for a total of 4 days. At the end of the incubation period, the cultures were examined for morphology, fusion, proliferation and growth. Examination by electron and light microscopy revealed that exposure to methanol for 1 day or more, reduced the incidence and completeness of fusion. The posterior epithelium was degenerated in unfused palates that were exposed for 1 day but was intact in unfused palates exposed for 4 days. A dose-related reduction in DNA content after 6 hours of exposure indicated that cellular proliferation was a specific and sensitive target. The dose that produced a significant reduction in DNA content was not specified by authors, but it appears that reductions were first noted at 312 mM after 6 hours of exposure and at the lowest dose (187 mM) after 12 hours of exposure. Reductions in total protein content were first noted after 12 hours of exposure but occurred to a lesser degree than DNA reductions. Measurement of \(^3\)H-thymidine uptake by scintillation counting demonstrated increased uptake in cultures exposed for 12 hours and decreased uptake in cultures exposed for 4 days. Examination of \(^3\)H-thymidine intake by autoradiography revealed a selective dose and duration-dependent decrease in labeled palatal mesenchymal cells in cultures exposed to \(\geq 468\) mM methanol for 1 day and \(\geq 250\) mM for 4 days. Uptake of \(^3\)H-thymidine was reduced in epithelial cells after 4 days of exposure to the highest dose (\(\geq 624\) mM). The authors also examined ethanol and found that it was more potent than methanol but did not produce toxicity through inhibition of cell proliferation.

Strengths/Weaknesses: The strength of this study is that a large range of doses was tested for various periods of time.

Some limitations were noted for this study. A single time point for DNA, protein and cell proliferation (as measured by tritiated thymidine uptake) was used. All cultures were treated with methanol at the beginning of culture and terminated at the same time leading to differences in the length of time between methanol treatment and analysis; the differences in this recovery time could account for some of the observations. The lowest concentration used in vitro corresponds to the highest dose used in vivo (83); in vivo that dose produced over 48% incidence of cleft palate, but there was no effect on palatal fusion in vitro.

Utility (adequacy) for CERHR evaluation process: The Panel’s confidence in these data are low due in part to the very high concentrations of methanol that were used. Additionally, previous in vivo work had shown that the sensitive period for cleft palate formation was much earlier than the time frame used in the current study. Although effects were demonstrated on palatal fusion in the present study, the differences in the sensitive period between in vivo and in
vitro exposure may indicate that different mechanisms are responsible for the defect. Despite these weaknesses, the study does point out the embryotoxic effects of methanol per se.

Andrews et al. (108) assessed the in vitro toxicity of formate in rat and mouse embryos using the same procedure they employed for the assessment of methanol toxicity (105) as described above. The purpose of this study was to compare the intrinsic toxicity of formate to that of methanol, to compare sensitivity in rats versus mice, and to assess the toxicity of formate when administered as the acid versus sodium salt. Crl:CD [Sprague-Dawley] BR rat (16–30/group) and Crl:CD-1 [ICR] mouse (17–29/group) embryos (9 and 8 days old, respectively) were incubated for 24 hours in media containing sodium formate or formic acid at levels resulting in equimolar concentrations of formate (2.95–44 mM). Exposures were also conducted for 48 hours in rat embryos treated with formic acid. As expected, addition of formic acid reduced the pH of media. In all treated embryos, dose-related trends were noted for reduced growth and development. Anomalies were observed in rat and mouse embryos treated with ≥11.8 mM formate through addition of either the salt or acid to the media. The most frequently observed anomalies involved the central nervous system (CNS) and included open anterior and posterior neuropore and erratic neural seam. Other anomalies observed with sodium formate treatment included rotational and tail defects in rats. In addition to the CNS defects described above, enlarged maxillary processes were observed in rat embryos treated with formic acid. A significant increase in embryolethality was observed only in rat and mouse embryos treated with formic acid (17.6–44 mM formate). The study authors concluded that formate exposure in rat and mouse embryos result in quantitatively and qualitatively similar results. Exposure to sodium formate for 48 hours in rats resulted in the same types of effects that occurred at a higher frequency compared to the 24-hour exposure. Formate (as either the sodium salt or the acid form) exposure produced embryolethality and dysmorphogenesis at molar concentration that were 4–10 fold lower than those observed with methanol. Acidosis may be partially responsible for embryotoxicity since treatment of cultures with formic acid appeared to lower the amount of formate ion needed to induce lethality compared to adding Na-formate. In closing the authors stated that developmentally toxic levels of formate are not likely to occur in humans as a result of environmental exposures. If this belief is true, rodents would be a good model for extrapolation to lower doses according to the study authors.

Strengths/Weaknesses: A strength of this study is that both formic acid and sodium formate were examined, as were effects of these compounds on pH. Potencies of the two compounds were compared in embryos of the two species.

A weakness of this study is that slightly different developmental stages were evaluated in the two species. Although the exact developmental stages covered by the culture period were different for the two species, neural tube closure was completed in embryos of both species during the culture period.

Utility (adequacy) for CERHR evaluation process: The panel’s confidence in these data are moderate to high for the same reasons as stated above for Andrews et al., (105). The study is useful because it allows for an examination of direct effects of compounds on embryonic growth and development in the absence of maternal confounds. This study, in combination with results from Dorman et al. (54) and Brown-Woodman et al. (109) increases confidence in the observation that high concentrations of formate produce embryotoxicity. However, as stated by the authors, the concentrations of formate required to produce adverse effects are unlikely to be achieved by the expected increased exposure to methanol that would result from its addition to gasoline.
An in vitro study by Brown-Woodman et al. (109) further examined the toxicity of methanol versus formate and evaluated the role of acidosis in developmental toxicity. Sprague-Dawley rat embryos (8–17/group; source not specified) were removed from dams on gd 10 and incubated for 40 hours in serum containing 0 or 51.3 – 411.7 mM methanol; a second group (9–19/group) was incubated in 0 or 3.74–27.96 mM formic acid. At the end of the exposure period, the embryos were assessed for viability and growth by examination of endpoints such as yolk sac vasculature, embryonic rotation, heartbeat, crown-rump length, somite number and protein content. No effect levels of 211.7 and 3.74 mM were identified by study authors for methanol and formic acid, respectively. Growth and developmental retardations were noted at higher concentrations for both methanol and formic acid. The lowest concentrations to produce embryotoxicity were 286.5 mM methanol and 18.66 mM formic acid. A series of experiments were next conducted to determine if toxicity associated with formic acid exposure resulted from a reduction in pH. To assess the effects of formate in the absence of a pH reduction, embryos were incubated in sodium formate or mixtures of sodium formate and formic acid at levels resulting in formate concentrations associated with embryotoxicity in the formic acid study. Embryos were also incubated in serum that was adjusted with hydrochloric acid to pH levels obtained with formic acid exposure. The results of these experiments indicated that both low pH and formate contribute to toxicity. The authors noted that embryotoxicity in this study occurred with serum methanol levels that were equivalent to those producing developmental toxicity in rats exposed through inhalation by Nelson et al. (82). In closing, the authors stated that occupational exposure to methanol at a time weighted average of 200 ppm would not result in blood levels of methanol or formate associated with developmental toxicity. However, the authors did note that pregnant women are at an increased risk of folate deficiency, a condition that may lead to a greater extent of formic acid accumulation.

Strengths/Weaknesses: The strengths of this study are that serum methanol concentrations were measured at several time points, pH effects were examined from two different approaches, and pH was measured at several time points during culture.

The weakness of this study is that only a small number of embryos were treated in each group.

Utility (adequacy) for CERHR evaluation process: The Panel notes that the developmental stage of exposure was different from that used by Andrews et al. (105, 108) in rats. However, the concentrations used are similar and results were very comparable. The Panel’s confidence in these data are moderate to high. In spite of the differences in study design and the low numbers of embryos used per group, the similarity of results to those reported by Andrews et al. (105, 108) in rats increases the Panel’s confidence in the reported results. Brown-Woodman et al. found that at sufficiently high concentrations, both methanol and formate were embryotoxic and that low pH contributed to the toxicity of formic acid in culture. These are important observations for the CERHR process. The study also provides useful dose-response data.

In vitro experiments to examine the role of formate in developmental toxicity were also conducted by Dorman et al. (54) as part of a series that also included in vivo studies that are addressed earlier in this section. On Gd 7, Crl: CD-1 ICR BR (CD-1) mouse embryos were explanted and cultured in media with 0, 62, 125, or 187 mM methanol for 12 hours. Gd 8 embryos were cultured with 0, 62, 125, 187, 250, or 375 mM methanol or 4, 8, 12, 20, or 40 mM formate for 12 hours. Embryos were examined on gd 9 for the size and shape of head, neuropore patency, somite numbers, and growth. At least 9 embryos were exposed/group and experiments were replicated a minimum of 2 times. In embryos explanted on gd 8, significant increases in prosencephalon lesions and branchial arch hypoplasia were observed with methanol treatment at ≥250 mM and increased numbers of cephalic dysraphisms were noted with exposure to 375 mM
methanol. A dose of 250 mM methanol is approximately equal to plasma methanol levels in mice inhaling 15,000 ppm methanol for 6 hours (223 mM). Treatment with 40 mM formate also resulted in increased numbers of cephalic dysraphisms and prosencephalon lesions. A plasma formate level of 40 mM greatly exceeds the level observed mice inhaling 15,000 ppm methanol (0.75 mM) but according to authors, can occur in humans with acute methanol toxicosis. Exposure to a 187 mM glycerol osmolality control resulted in prosencephalon and branchial arch defects but no neural tube effects. Dose related reductions in embryo growth and rotation were also reported for methanol and formate exposure. The findings of this study, in addition to those obtained in in vivo experiments described above, led authors to concluded that “...methanol and not formate is the proximate teratogen in pregnant CD-1 mice exposed to high concentrations of methanol vapor.”

Strengths/Weaknesses: This study design is good for comparing effects of methanol and formate. Strengths of the study design include the selection of methanol and formate concentrations that were calculated to approximate blood levels that occur under typical rodent exposure scenarios. Exposure concentrations approximate peak maternal blood methanol levels following 15,000 ppm exposure in vivo.

A weakness is the lack of information on formate and methanol levels during the culture period and the limited information on pH. The panel also noted that embryos cultured on gd 7 did not grow well and stated that those results are questionable.

Utility (adequacy) for CERHR evaluation process: The panel’s confidence in these studies is high. Results strongly suggest that formate is not involved in the teratogenicity of methanol in mice. The exposures in the Dorman study (12 hours) were shorter than those used by Andrews et al. (108) (24 and 48 hours). Also, the investigators examined different end points, so it is difficult to compare the studies directly. However, results of the in vitro studies are similar to Andrews et al and Brown-Woodman et al.

Andrews et al. (110) conducted in vitro studies with rat embryos to compare toxicities of methanol and formate alone and in combination. The studies were based on a developmental scoring system that takes into account embryonic growth and stages of development. Doses from previous in vitro experiments (106, 108) were used in a dose-addition predictive model to estimate doses of methanol, formate, and methanol/formate mixtures that would reduced developmental scores by 13.5% (Simplex 1) and 27% (Simplex 2). Methanol/formate doses were 0/0, 6.11/0.56, and 0/0.89 mg/ml (0/0, 191/0, 70.2/12.2, 0/19.3 mM) in Simplex 1. In Simplex 2 doses were 0/0, 8.75/0, 5.90/0.49, 2.25/1.12, and 0/1.51 mg/ml (0/0, 273/0, 184/10.6, 70.2/24.3, and 0/32.8 mM). Gd 9 Sprague-Dawley (Crl:CD [SD] BR) rat embryos were treated for 48 hours and examined for signs of toxicity. Fifteen to 26 embryos were examined in each group. Treatment with individual compounds produced significant decreases in development score, somite number, crown-rump length, and head length in Simplex 1 and Simplex 2. In Simplex 2, the methanol/formate mixtures also produced significant decreases in those parameters. However, in all cases the reductions following exposure to either methanol or formate alone were greater than reductions observed with methanol/formate mixtures. The observation led authors to conclude that methanol and formate have an infra-additive (less than additive) interaction and produce effects through different mechanisms of toxicity.

Strengths/weaknesses: A strength of this study was that a sufficient number of embryos per group was examined. In addition, the combined effect of methanol and formate was investigated; such a mixture of the two compounds is the most likely occurrence in vivo. The embryotoxicity
of the mixtures was predicted based on the results of previous studies; the results of either compound alone were almost exactly as predicted.

Some limitations were noted for this study. Previous work had demonstrated that the rat was less sensitive than was the mouse to the effects of methanol or formate; however, rather than choosing the most sensitive species for this study, the authors chose to study the effect of mixtures in the rat. Little information is presented in the Methods regarding the actual concentrations of methanol and formate used in these studies. In Fig. 6 of the study, data are presented in the figure that are not found (or discussed) elsewhere in the manuscript.

**Utility (adequacy) for CERHR evaluation process:** The Panel’s confidence in these data are moderate to high. The methanol and formate concentrations used gave almost exactly the results predicted by previous work showing the reproducibility of the results and increasing confidence in them.

### 3.3 Utility of Data

### 3.4 Summary of Developmental Toxicity

**Human data**

A single study (69) was reviewed in which occupational exposures were determined in women who gave birth to infants with and without cleft lip or palate. The study did not find an association between methanol exposure and oral clefts but several limitations in the study were noted including: small number of subjects exposed to methanol, lack of individual exposure data, and confounding by other chemical exposures. Because of these limitations the Panel judged the study results to be uncertain and concluded there are insufficient human data upon which to evaluate the developmental toxicity of methanol.

The Expert panel reviewed four epidemiological studies that examined folate supplementation and cleft palate (71-74). The Expert Panel concluded that in the aggregate the studies suggest a reduced risk of oral clefts following supplementation with vitamins containing folic acid. The epidemiological findings weakly support the hypothetical mechanism of action that methanol reduction of folate activity in the rodent causes oral cleft defects. However, that extrapolation is difficult due to various interspecies differences, including different folate levels between rodents and humans.

**Experimental animal data**

The panel reviewed developmental toxicity studies that were performed in rats, mice, and non-human primates. Results of these reviews are summarized below by species.

**Rat.** The results of Nelson et al. (82) are sufficient to conclude that inhalation exposure of Crl:Sprague-Dawley rats to 20,000 ppm methanol vapor for 7 hours/day on gd 7–15 causes prenatal developmental toxicity as evidenced by reduced fetal weight, increased litter incidence of exencephaly and encephalocele and skeletal malformations. This dose caused clinical signs of maternal intoxication in early days of exposure but no other maternal effects. Developmental toxicity was also observed following exposure to 10,000 ppm for 7 hours/day on gd 1–19 as evidenced by statistically significant reductions in fetal body weight. The Expert Panel designated 10,000 ppm as a maternal NOAEL and 5,000 ppm as a fetal NOAEL. Blood
methanol levels were determined in non-pregnant rats with exposures similar to the pregnant dams. Deficiencies in design or completeness of data presentation led the Expert Panel to conclude that the studies of Cummings et al. (84) and Youssef et al. (85) were of limited utility in this evaluation.

Stanton et al. (89) exposed Long-Evans rats to 15,000 ppm methanol vapor for 7 hours/day on gd 7–19 and observed a modest but statistically significant reduced bodyweight in pups at birth, weaning, and postnatal day 35. Effects were not observed postnatally in the pups who were subjected to a range of tests for neurobehavioral function; however, small sample size limits confidence in these negative results.

Offspring from Long-Evans dams that drank water containing 2% methanol on either gd 15–17 or 17–19 were observed to have an increased latency to effect nipple attachment or to reach their home nesting site (88). In a later study, Weiss et al. (90) determined neurological function in Long-Evans pups following 6-hour/day exposure to 4,500 ppm methanol vapor to dams from gd 6 through pnd day 21 and to pups from pnd 1–21. No effects were observed on dam weight during gestation, litter size, or postnatal pup weight gain to pnd 18. No effects were observed in latency to nipple attachment or olfactory sensory capabilities. Changes in motor activity were variable or inconsistent.

In the aggregate, the postnatal data from three studies in Long-Evans rats give no indication of maternal effect or effects on pup viability following prenatal doses of up to 15,000 ppm methanol vapor or pre and postnatal exposure of 4,500 ppm. Modest reduction in body weight was observed postnatally in pups whose dams had been exposed to 15,000 ppm methanol vapor on gd 7–19. There are negative or inconsistent data with respect to developmental neurotoxicity. However, the data are insufficient to conclude that neurobehavioral endpoints have been completely and effectively assessed.

Mouse. The studies of Rogers et al. (83) are sufficient to conclude that prenatal exposure of Crl:CD-1 mice to methanol vapor at doses of 2,000 ppm or greater for 7 hours/day on gd 6–15 causes developmental toxicity as evidenced by cleft palate, exencephaly and skeletal malformations. The initial appearance of malformations were dose-associated with cervical ribs seen at 2,000 ppm, cleft palate at 5,000 ppm and exencephaly at 10,000 ppm. Effects on the number of live pups per litter and fetal weight were seen at 7,500 and 10,000 ppm, respectively. The developmental toxicity NOAEL was 1,000 ppm. The maternal NOAEL was judged to be 15,000 ppm. Rogers et al. also established dose comparability across inhalation and oral gavage exposure by demonstrating that twice daily gavage with 2,000 mg/kg bw methanol on gd 6–15 results in a methanol blood level and developmental pattern of response similar to that in mice exposed to 10,000 ppm methanol vapor. No postnatal studies were performed in the mouse.

A considerable literature (10 reports or publications) was reviewed relevant to characterizing mode of action of methanol’s effects on developmental toxicity in the mouse. Two laboratories conducted phase specificity studies in CD-1 mice exposed to teratogenic concentrations of methanol through inhalation (99, 100). The majority of findings were consistent between laboratories. As expected, methanol exposure during the period of neural tube development and closure (gd 7–9) resulted in exencephaly. The incidence of cleft palate was also increased following exposure during gd 7–9, despite the fact that cleft palate closure occurs later in gestation. Gd 7 was found to be the most sensitive day for developmental effects since treatment on that day resulted in the greatest incidence of resorptions, exencephaly, cleft palates, and vertebral and rib defects. Bolon et al. (101) subsequently identified a putative mode of action (reduced proliferation) and targets of toxicity (neuroepithelium, mesoderm, neural crest) for
methanol-induced neural tube defects in embryos of CD-1 mice exposed to 15,000 ppm methanol vapors for 6 hours/day from gd 7–9. Connelly and Rogers (102) studied whether cervical vertebrae were associated with homeotic shifts and concluded that methanol can alter segment patterning in CD-1 mouse embryos, resulting in posteriorization of cervical vertebrae. Dorman et al. (34) reported an important series of experiments designed to investigate the role of methanol and its metabolite, formate, on development using CD-1 mice. Using a dose of sodium formate (750 mg/kg bw) that is equivalent to the formate concentration following inhalation of 15,000 ppm methanol, no exencephaly was observed. However, 15,000 ppm methanol exposure is a dose that produces exencephaly in mouse fetuses, thus suggesting exencephaly in mice requires direct exposure to methanol as opposed to only accumulation of formate. Two studies examined the impact of folate pools on methanol-induced developmental toxicity in CD-1 mice fed diets with adequate or reduced folate levels (67, 70). In dams fed folate deficient diets, maternal and fetal hepatic folate levels were reduced. Folate deficiency enhanced the toxicity of methanol as noted by increased incidences of cleft palate and exencephaly in mice treated with methanol at 4,000–5,000 mg/kg bw/day. The Expert Panel noted that the folate deficiency studies were limited due to a lack of pair-fed controls. Using in vivo intrauterine microdialysis, Ward (53) collected data in mice and rats to indicate that at doses that are developmentally toxic (100 or 500 mg/kg or 1,000 mg/kg/hr, intravenously) there is also a reduced uteroplacental blood flow. They postulated that, under these conditions, hypoxia may have a role in the etiology of embroyotoxic effects of methanol. Ward and Pollack (111) compared the rate of methanol metabolism in pregnant and non-pregnant mice and rats and fetal mice. Pregnancy appeared to reduce metabolic rate by ~15%; metabolic rate in mouse liver homogenate was about two-fold greater than rat liver homogenates. Metabolic rates in fetal homogenates were only 5% of those seen in adults. These fetal data are consistent with earlier observations on alcohol and aldehyde dehydrogenases in rat fetuses (104).

**In Vitro Rodent Studies.** To gain a better understanding of mechanisms of toxicity, 7 in vitro studies were conducted with methanol or formate. Exposure of rat and mouse embryos to methanol demonstrated effects consistent with those observed in vivo with a greater intrinsic sensitivity of mouse versus rat embryos; developmental toxicity in rats and mice was noted with methanol concentrations of ≥250 mM and ≥62.4 mM, respectively (105, 106). Increased cell death was noted in mouse (dose not clear) and rat (499 mM) embryo structures associated with malformations following in vivo exposures; however increased cell death was not noted in neural tube regions, suggesting a mechanism other than cell death for neural tube defects (106).

Treatment of mouse and rat embryos with formate demonstrated effects similar to those of methanol but the formate concentrations that caused effect (11.8–40 mM) were 4–10 fold lower (54, 108, 109). Toxicity appeared to be induced by both the formate ion and resulting acidosis. In a study testing mixtures of methanol and formate in rat embryos, it was found that the effects of the two compounds were less than additive (110). According to Andrews et al. (108) and Brown-Woodman et al. (109), the formate levels that produced toxicity in in vitro studies are not likely to occur in humans following environmental or occupational exposures.

**Rat/Mouse Comparison.** In comparing similar studies in rodents, the data are sufficient to demonstrate that exposure to high concentrations of methanol vapor can cause similar prenatal developmental toxicity and frank malformations. There is good, but limited, data to indicate that the nature and incidence of fetal effects correlates with blood methanol concentration when methanol exposure is by inhalation or the gavage route. Mice are judged to be the more sensitive species since effects were noted at lower chamber concentration doses than rats. However, at equivalent chamber concentrations, mice had higher maternal blood methanol levels. Table 3-4 compares NOAELs from the definitive prenatal developmental toxicity studies in rat and mouse.
Table 3-4. Nominal Exposure Levels to Methanol Vapor and Corresponding Blood Methanol Levels in Rats (82) and Mice (83).

* Maternal blood methanol level

Cross species comparisons as to postnatal effects are not possible as there are only data in rats.

Nonhuman Primate. Burbacher et al. (93) studied the effects of methanol on general and neurobehavioral development of M. fascicularis infants whose mothers were exposed to methanol vapors (200–1,800 ppm for 2.5 hours/day) throughout gestation. Duration of pregnancy was reduced in primates exposed to methanol vapors; however, no dose response pattern was observed and gestation lengths were within normal ranges. Adult monkeys experienced no effects on weight gain or overt toxicity as a result of methanol exposure. Normal weight gain and physical development was observed through the first year of infant life. The relationship of prenatal methanol exposure of dams (1,800 ppm) to wasting disease observed in a 12 and a 17-month-old offspring is not clear. Neurobehavioral performance was similar in control and methanol groups in seven of nine tests. A mild, statistically significant, dose-related delay in sensorimotor function was seen in males and also in both sexes when data were combined. All three groups of prenatally methanol exposed infants failed to show a preference for novel social stimuli; however there was no evidence of a dose relationship nor was a significant effect observed across all methanol groups. No effects on general health and development, including learning performance were observed in Macaca arctoides monkeys fed with up to 2,700 mg/kg bw/day aspartame (equivalent to 270 mg/kg bw/day methanol) during the first 9 months of life (97, 98).
4.0 REPRODUCTIVE TOXICITY

This section contains reviews of original studies. Some tables are presented to assist the reader in the interpretation of the data. Smaller tables are included in the text for the reader's convenience and are designated as Table 4-1, 4-2, etc. Larger tables are included in Section 7 and are designated as Table 7.4-A, 7.4-B, etc.

4.1 Human Data

There were no human data located.

4.2 Experimental Animal Toxicity

Because methanol is so commonly used in industry, Cameron et al. (112) studied the effects of methanol exposure on the male reproductive system. Groups of 5 mature male Sprague-Dawley rats/group [source and age not specified] were exposed to methanol vapors [99.5% purity] at 0, 200, 2,000, or 10,000 ppm for 8 hours/day, 5 days/week, for 1, 2, 4, or 6 weeks (Table 7.4-A). [There was no discussion of rational for dose selection.] Five control animals were exposed to air only. Animals were sacrificed 16 hours following the last exposure and serum levels of testosterone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) were measured by radioimmunoassay (RIA). [The number of animals examined at each time period was not specified.]. Statistical significance was evaluated by Student's t-test. Significantly reduced levels of testosterone were noted at week 2 for the 200 ppm group and at week 6 for the 200 and 2,000 ppm group. The greatest reduction in testosterone level occurred in the 200 ppm group at week 6. A significant increase in LH levels was noted in the 10,000 ppm group at week 6, the only time point of measurement. To determine the cause of reduced testosterone levels, the authors exposed 5 mature male rats/group to 200 ppm methanol vapors for 6 weeks, intravenously injected the rats with $^{14}$C-testosterone 16 hours following the last exposure, and measured levels of plasma $^{14}$C-testosterone. The experiment demonstrated that methanol does not increase the rate of testosterone removal from blood; authors therefore concluded that methanol exposure effects the rate of testicular testosterone synthesis.

Strengths/Weaknesses: The strengths of this study are that the exposures appear to have been well-controlled as the variations around the target concentrations appear relatively small and the purity of methanol was reported.

Some weaknesses were noted for this study. The lack of detail regarding measurement of chamber concentrations reduces confidence in the chamber concentrations reported. It was not stated if rats were randomly assigned to treatment groups and the ages of rats were not reported. The number of rats used is quite small for hormone studies (n=5), thus increasing the chances of finding spurious effects. Because of inter-animal variations, at least 15 animals are required and 20 per group is measurably better when doing single-point hormone evaluations, (113, 114). The time between the end of exposure and death is long. The animals were killed 16 hrs after the end of the last exposure, by which time circulating methanol levels would have declined, and any compensatory change in hormone levels would have had time to occur. Thus, the reader is not sure whether the effects seen are due to methanol exposure, or if they are “rebound effects” resulting from the absence of the main methanol effect. The data in the Cameron et al., 1985 paper (discussed below) are consistent with a possible rebound effect, although how a rebound would result in depressed values and in an inverse dose-response is not immediately clear. Methodologic details are sparse at best. For example, no details of the RIA assay are provided, so
the Panel has little idea of the confidence in the assay that generated the numbers. Of greater concern is the fact that the statistics are inappropriate (hormone data are almost never normally distributed, and repetitive t-tests assures too many false positive comparisons). Minimal data or methods were provided for the radiolabeled clearance study, which prevents significant weight being placed on these data. Lastly, the panel noted the lack of LH measurements for most time periods. The inverted dose-response for testosterone is intellectually challenging to interpret, as no known mechanism can be invoked. The fact that the pattern of changes in LH are mirrored by change in testosterone suggests that the primary effect is on the CNS, which drive changes in testosterone production, but the fact that normal LH levels are coupled with testosterone values that are 60% of control suggest that there are peripheral effects as well.

Utility (adequacy) for CERHR evaluation process:
The Panel’s confidence in these data is low because of the weaknesses of this study and limited reporting of data. The Panel is not confident in the link between exposures and effects reported by this study. The data might be useful in confirming data from another study without these limitations.

In a second study, Cameron et al. (115) assessed 4 alcohols (methanol, ethanol, n-propanol, and n-butanol) to determine the effects on male hormonal levels. Groups of five male mature Sprague-Dawley rats [source and age not specified] were exposed to methanol vapors [99% purity] at 0 or 200 ppm for 6 hours/day for 1 day or 1 week (Table 7.4-B). [The basis for dose selection was not discussed]. Five control animals were exposed to air only. Animals were sacrificed either immediately or 18 hours after the last exposure period. Serum levels of testosterone, LH, and corticosterone were measured by RIA. [The number of rats examined was not specified.] Statistical significance was determined by Student’s t-test. A significant reduction in testosterone (T) level was noted immediately following the first 6 hour exposure for each of the 4 alcohols. Levels returned to control values after 18 hours in all but the n-butanol group. No other changes in hormone levels were observed. [According to the Expert Panel, these data seem to suggest that methanol affects both peripheral testosterone production and central LH secretion, as LH was not elevated when testosterone was reduced].

Strengths/Weaknesses: Many of the strengths and weaknesses for this study are similar to those in the previous study (112). A strength of this study is that some animals were killed immediately after the end of exposure, thus addressing one of the concerns noted for the Cameron et al. 1984 (112) study. There does seem to be some recovery of testosterone levels that occurs within 18 hours after ceasing exposure. A second strength is that there are both LH and testosterone data for these time points, allowing us to get a sense of site(s) of action.

The weaknesses of this study include no reporting of chamber concentrations or methods used to measure the concentrations, insufficient reporting of methods, use of a small number of animals, and no information about assay performance (a relatively minor point). See previous study (112) for an explanation about these limitations.

Utility (adequacy) for CERHR evaluation process: Some of the data from the Cameron et al. 1985 study were apparently similar to those reported in the Cameron et al. 1984 (112) paper, which slightly increases the Panel’s confidence in the 1984 paper. Collectively, the Panel believes that the data from the Cameron et al. 1985 (115) study have more value for the Evaluative Process, and places moderate confidence in these data. However, the study is still limited by the small numbers of animals per group. These two papers (112, 115) are viewed as best used to corroborate other data.
Lee et al. (116) noted the lack of dose and time-related responses of testosterone levels in rats exposed to methanol in the Cameron et al. (112, 115) studies. Therefore, they conducted a series of studies to further investigate the testicular effects following methanol exposure. In the first study, 8-week-old male Sprague-Dawley [Crl: CD(SD)BR VAF/Plus] rats (n=9–10/group) were exposed to 200 ppm methanol [purity not specified] by inhalation for 8 hours/day, 5 days/week, for 1, 2, 4, or 6 weeks (Table 7.4-C). [It is assumed the dose level was selected because it was the dose evaluated by Cameron et al. 1994, 1995]. Nine control rats were exposed in chambers to clean filtered air. Serum testosterone levels were measured by RIA at the end of exposure in 9–10 rats/exposure period between 9:00-11:00 a.m. in order to avoid diurnal fluctuations in testosterone levels. Statistical significance was determined by one factor analysis of variance followed by Student’s t-test. Methanol treatment had no effect on serum testosterone concentration, the gross appearance of reproductive tissues, or testes or seminal vesicle weight. These testes were next incubated in vitro and it was determined that methanol treatment had no effect on testosterone production, with or without the addition of human chronic gonadotropin hormone.

In an additional experiment Lee et al. (116) determined if testicular lesions indicating changes in testosterone levels were present in rats exposed to methanol. These experiments also examined the effects of both dietary folate intake and age. Four week-old male Long-Evans [Crl: (LE) BR VAF/Plus] rats were fed diets with sufficient or reduced folic acid- (3–4 mg/kg or <0.05 mg/kg with 1% succinylsulfathiazole, respectively). At 7 months of age, rats (≥9/group) were exposed to methanol vapors [purity not specified] at 0, 50, 200, or 800 ppm for 20 hours/day for 13 weeks (Table 7.4-D). A group of 15-month-old rats (8–12/group) were exposed to 0 or 800 ppm methanol vapors for 20 hours/day for 13 weeks. [Treatment of controls was not discussed, no rational was provided for dose selection.]. The authors stated that acidosis and visual impairment occurred in the rats fed low folic acid diets and exposed to methanol. At the end of exposure, testes were removed, weighed, and preserved in 10% neutral buffered formalin, embedded in glycol methacrylate, and stained with PAS or methylene blue. The testes from 8–12 rats/group were examined. [There was no statistical evaluation of histological effects]. At the end of exposure, there were no methanol-induced, dose-related increases in testicular lesions or changes in testes or body weights in 10-month-old rats fed diets with sufficient or reduced amounts of folate. The rats that received sufficient folic acid and were 18 months old at the end of exposure also experienced no dose-related increases in testicular lesions. However, in the 18-month-old rats fed reduced folic acid diets, methanol exposure increased the incidence but not severity of age related testicular lesions. Specifically, mild, age-related testicular degeneration, consisting of subcapsular vacuoles in the germinal epithelium of seminiferous tubules, was noted in 3/12 control rats and 8/13 rats exposed to 800 ppm methanol. [This lesion appeared to the Panel to be more properly a fixation-induced shrinkage artifact. The Panel could not interpret an increased likelihood to shrink upon fixation as an adverse treatment-related health effect.]. Additional lesions included atrophy of seminiferous tubules in 1 rat and Leydig cell hyperplasia in another rat of the 800 ppm methanol group.

**Strengths/Weaknesses:** The ages of animals were appropriate. Strengths include evaluation of hormone status by several means: 1) direct RIA measure of testosterone (complete with assay performance data), 2) weight of androgen-sensitive organs, 3) an assessment of the capability of in vivo exposed testes to produce testosterone in vitro, and 4) histologic assessment of the seminiferous epithelium, which would show a specific low-androgen lesion if a biologically-meaningful reduction in testosterone had occurred. The concordance among all these endpoints confers great credibility to the conclusion of no methanol effect on testosterone. The methods of fixing and preserving the testis were sufficient, although not entirely without some artifact. It appears as though some of the vacuoles are shrinkage-induced artifacts that may occur during
fixation. However, the fixation methods are better than those used by many investigators. In addition, the authors used sufficient animals to allow confidence in the data, randomly divided animals into treatment groups, provided some details on the analytic methods for verifying chamber methanol concentrations, and used appropriate statistics for comparing testosterone levels.

A limitation of this study was the number of animals in which testosterone levels were measured. The variances in Table 2 of the study are all large (in some cases, almost the same value as the mean), indicating large inter-animal variability. However, this is compensated by the other testosterone-dependent measures (seminal vesicle weight, in vitro testosterone production, and testis histology), all of which are concordant with no change in testosterone production. A second limitation was that testosterone was not measured in folate-reduced rats, but only in folate-sufficient rats. If reduced-folate rats are a physiologically-relevant surrogate for methanol-exposed humans, it would have been useful to have measured serum testosterone in folate-reduced rats. Lastly the purity of methanol was not reported.

Utility (adequacy) for CERHR evaluation process: The Panel has high confidence in the methods and data resulting from these studies. The Panel considers that these data collectively show little or no ability of methanol, at 200 ppm in SD rats, or up to 800 ppm in Long Evans rats, to reduce testosterone signaling in vivo. The apparent increase in aging changes in the 800 ppm-exposed LE rats is of uncertain significance.

Cooper et al. (117) studied the effects of methanol exposure on rat serum pituitary hormone levels in an attempt to replicate the findings of Cameron et al. (112, 115) and to determine if hormone levels were affected by handling of animals during inhalation exposure. The experiments used male Long-Evans hooded rats (Harlan Sprague-Dawley) that were or were not acclimated to exposure and handling conditions. Rats were acclimated by removing them from their home cages and transferring them to inhalation chambers for two weeks. In the first experiment 10 rats/group (90 days old) were exposed to methanol vapors (Optima Grade from Fisher Scientific (2001), >99.9% purity) at levels of 0, 200, 5,000, or 10,000 ppm for 6 hours. The doses were based on those used in studies conducted by Cameron et al. (112, 115), Nelson et al. (82), and Infurna and Weiss (88). A control group consisted of sham exposed rats. One group of rats was sacrificed immediately following exposure and a second group was sacrificed 18 hours later (24 hours after the start of exposure). Statistical significance was evaluated by analysis of variance; when significant interactions were observed further comparisons were made by Student’s t-test. Serum methanol levels in acclimated rats immediately after exposure were measured at 0.0074, 0.6798, or 1.4678 mg/ml (0.231, 21.2, or 45.8 mM), in the 200, 5,000, and 10,000 methanol treatment groups, respectively. At 24 hours following exposure, serum methanol levels exceeded the detection limit only in the in the high dose group and were measured at 0.2348 mg/ml (7.32 mM). Analyses were conducted to measure serum levels of testosterone, luteinizing hormone (LH), and follicle stimulating hormone (FSH) and testicular interstitial fluid testosterone (n=10) by RIA in 10 rats/group. Results of hormone analyses are illustrated in Figure 4-1. The following discussion on serum hormonal levels includes only effects that were statistically significant. Immediately after exposure, change in LH level was the only effect noted. The non-acclimated rats exposed to MeOH at 5000 ppm showed an apparent = 40% reduction in LH. An increased LH level in non-acclimated versus acclimated controls indicated that higher LH levels were associated with handling of the rats, but this was not seen at 24 hrs. after the start of the last exposure. Methanol treatment resulted in an increased LH level in acclimated rats exposed to 10,000 ppm when killed immediately after exposure, but reduced LH at 5000 ppm in non-acclimated rats. At 24 hours, a methanol-induced increase in LH was noted in acclimated rats of the 10,000 ppm group. At 24 hours, the serum testosterone level was reduced in acclimated rats.
exposed to 10,000 ppm methanol but increased in non-acclimated rats exposed to 5,000 ppm methanol. Changes in testosterone levels occurred in opposite directions in acclimated versus non-acclimated rats of all methanol treatment groups. Results were similar for testicular interstitial fluid testosterone levels. The authors noted that the experiment did not reproduce the results of Cameron et al. (112, 115) because exposure to 200 ppm methanol did not reduce serum testosterone levels.

In the second experiment, Cooper et al. (117) measured serum methanol, testosterone, LH, and prolactin levels in 10, 90-day-old male Long-Evans rats/group exposed to 5,000 ppm methanol vapors for 1, 3, or 6 hours. Unless otherwise specified, the details were the same as the previous experiment by Cooper. Measurements were conducted immediately after exposure. Serum methanol concentrations in acclimated rats were 0.2416, 0.3974, and 0.7518 mg/ml (7.54, 12.4, and 23.5 mM) after exposure for 1, 3, and 6 hours respectively. In non-acclimated rats, serum methanol concentrations after 1, 3, and 6 hours of exposure were 0.2988, 0.683, or 0.8732 mg/ml (9.33, 21.3, 27.3 mM), respectively. The increased concentrations of serum methanol in non-acclimated rats after 3 or 6 hours of exposure were statistically significant. Methanol treatment had no effect on serum testosterone and LH levels when compared to unexposed controls in the same acclimation group. However, both testosterone and LH levels were significantly higher in non-acclimated versus acclimated rats with or without methanol exposure. Methanol treatment significantly increased serum prolactin levels in comparison to non-exposed controls of the same acclimation group and prolactin levels were highest in the non-acclimated rats at 1 and 6 hours of exposure. The authors concluded that methanol exposures can affect serum hormonal levels, but the magnitude and direction of change depends upon the handling of the animal.

Strengths/Weaknesses: The strengths of these studies are that age of the animals were appropriate, significant methodological detail was provided, appropriate statistics were used, methanol purity was reported, methanol concentrations in chambers were monitored and reported, internal evaluations (method-checks on methanol analyses and RIA assay performance) were conducted, serum methanol levels were measured, a sufficient number of animals was used, and the animals were randomly divided into exposure groups.

A limitation of the studies is that numbers of animals (n=10) are barely sufficient for most hormone measures. These studies are limited primarily by the complexity of the study design. The authors themselves note that handling appears to change both the direction and magnitude of any hormone changes, which makes the interpretation of any methanol effect (in the words of the authors) “most difficult.”

Utility (adequacy) for CERHR evaluation process: While the Panel had high confidence in the methods of the investigators and the resulting quality of these data, it is difficult to put these data into perspective with other data in the literature. It appears that methanol inhalation is a stressor (based on serum Prolactin levels), and any effects of methanol exposure on testosterone require high levels of exposure (5000 ppm or greater), and may be modified by how well-acclimated the rats are to the exposure apparatus and process. Taken at face value, these studies appear to support the lack-of-effect noted by Lee et al. (116).

Ward et al. (118) examined sperm morphology in 4-month-old Crl: B6C3F1 mice that were gavaged with 1000 mg/kg bw/day methanol [purity not specified] in water (n=10) or water (n=5) for 5 days. The dose resulted in 10 times the methanol level found in formalin, the main interest of the study. Non-parametric tests were used to determine significance of differences among all treatment groups (Kruskal-Wallis test) and between groups (Mann-Whitney U test). Treatment
with methanol significantly increased the number of mice with “banana-type” sperm morphology, an effect of unknown biological significance.

There were no histopathological effects observed in the reproductive organs of 15 male and female Crl: Sprague-Dawley rats/sex/group (4–5 weeks-old) that were exposed to 2,500 ppm methanol vapors for 6 hours/day, 5 days/week for 4 weeks (66). A detailed summary of the study and a discussion of strengths/weaknesses and utility is included in Section 2.2.2.

In 2 cohorts of Macaca fascicularis monkeys (6/group/cohort) that were exposed to methanol vapors at up to 1,800 ppm, there were no effects on menstrual cycles or conception rate (41, 93). A non-dose-related reduction in gestation length and increased complications during birth were noted in monkeys treated with 200–1,800 ppm methanol and are discussed in greater detail under Section 3.2.2. A discussion of the strengths/weaknesses and utility is included in Section 3.2.2.

A 2-generation study conducted by NEDO (1, 2) found no effects in male and female Sprague-Dawley rats that inhaled up to 1,000 ppm methanol for 20 hours/day. However, the study was not available to the Expert Panel for review. ILSI reviewed the study and concluded that it was not adequately reported and that findings need to be verified by other laboratories.

4.3 Utility of Data

4.4 Summary of Reproductive Toxicity

There were no human data located.

Four studies examined serum hormone levels in male rats exposed to methanol through inhalation and two studies included a histological evaluation of reproductive organs. The definitive work was a study by Lee et al. (116). The Panel had high confidence in the results of their study that exposed 8 week-old Sprague-Dawley rats to 200 ppm for 8 hours/day for 1–6 weeks and observed no effect on testosterone, weight of androgen sensitive organs, capability of in vivo-exposed testes to produce testosterone in vitro and lack of gross morphological effect. In the second part of the Lee et al. study, normal and folate-deficient, methanol sensitive Long-Evans rats exposed to 800-ppm methanol for 20 hours/day, 7 days per week for 13 weeks had no adverse testicular histology at 10 months of age. A higher incidence but not severity of age-related testicular degeneration was observed in the folate-deficient, 18-month-old rats exposed to 800 ppm methanol for 13 weeks; but the incidence of age-related testicular lesions in the 18-month-old folate-sufficient rats was equal in treated and control rats. The results of Poon et al. (66) who found no lesions in the reproductive organs of 4–5 week old male and female Sprague-Dawley rats that inhaled 2,500-ppm methanol vapors for 6 hours/day for 4 weeks were consistent with findings of Lee et al. (116) in ten-month old rats. Their methodology was adequate to detect major testicular effects and of modest utility to detect more subtle effects. The studies examining serum hormone levels (112, 115) were found to be of limited utility because of deficiencies in experimental design and incomplete reporting of data. Their results were not confirmed by Lee et al. (116) or by Cooper et al. (117). Cooper et al. found that treatment with ≥5,000 ppm methanol for six hours could affect serum levels of LH, testosterone, and prolactin. However, the magnitude of the response, and in the case of LH and testosterone, the direction of the response depended on whether or not the animal was acclimated prior to treatment. These data underscore the need to cautiously interpret studies that reveal hormone effects and to consider the impact that experimental conditions may exert upon results.
One study examined reproductive function in female *Macaca fascicularis* monkeys exposed with up to 1,800 ppm methanol vapors for 2.5 hours/day during a premating and mating period (about 180 days) and the entire pregnancy (about 168 days). Burbacher et al. (41, 93) found no effects on menstrual cycles or conception rates. Variances within the normal range of gestation length were noted but were judged by most Panel members to be of uncertain toxicological significance.

Data are not available to permit a complete and effective assessment of the reproductive toxicity of methanol. However, there are several lines of evidence in male Sprague Dawley rats to indicate that exposure to 200 ppm methanol vapors for 13 weeks is without effect on reproductive hormones (or on tissues sensitive to effects of these hormones). A study that assessed the morphology of reproductive tissues in rats of both sexes exposed by inhalation to 2,500 ppm methanol for 4 weeks was without effect. Exposure of folate-deprived rats (a model considered more analogous to human metabolic capability) to 800 ppm for 13 weeks also appeared to be without effect on testicular morphology at 10 months of age, although the Panel recognizes that the methods employed have only modest ability to detect subtle effects. Finally, there are sufficient data in female sub-human primates to conclude that exposure for 2.5 hours per day to 1800 ppm methanol vapor was without effect on menstrual cycle, conception rate, or ability to sustain pregnancy. Collectively, these data from animal studies suggest that methanol does not appear to be a significant reproductive toxicant in rats and non-human primates.

<td>Cameron et al. (115) exposed mature Sprague-Dawley male rats (Source not specified) to methanol vapors for 6 hours/day for 1 day or 1 week. Methanol concentrations in inhalation chambers were verified. One group of animals was sacrificed immediately after each exposure period and a second group was sacrificed 18 hours following the last exposure period. Serum levels of testosterone, luteinizing hormone (LH), and corticosterone were measured.</td>

<tr>
<td>Lee et al. (116) exposed mature Sprague-Dawley male Crl:CD(SD) BR VAF/Plus rats (8-weeks old) to air or methanol vapors for 8 hours/day, 5 days/week, for 1, 2, 4, or 6 weeks. Methanol concentrations in inhalation chambers were verified. The animals were sacrificed on the last day of exposure between 9:00 and 11:00 am. Testes and seminal vesicles were weighed and serum levels of testosterone were measured. Testes were examined for in vitro production of testosterone with and without human chronic gonadotropin.</td>

<tr>
<td>Lee et al. [116] fed 4-week-old Crl: Long-Evans (LE)BR VAF/Plus rats folate sufficient (3–4 mg folic acid/kg) or folate-reduced (&lt;0.05 mg folic acid/kg with 1% succinylsulfathiazole) diets. At ~7 months of age, the rats were exposed to air or methanol vapors for 20 hours/day for 13 weeks. Methanol concentrations were monitored inside inhalation chambers. At the end of the exposure period (10 months of age), body and testes weight were measured and testes preserved in 10% neutral buffered formalin were examined histologically. The same experiment was conducted in rats that were ~15 and 18 months old at the beginning and end of methanol exposure respectively.</td>
